▲ Figure 96) Mechanisms of UV-induced immunosuppression. Langerhans cells (LC) in the skin are activated by UV radiation and migrate to the lymph node, where they present antigen to CD4+ T cells. Activated CD4+ T cells differentiate into regulatory T cells, which suppress delayed-type hypersensitivity (DTH) and contact hypersensitivity (CHS) responses. UV radiation also activates NKT cells, which suppress tumor rejection. MNC II, major histocompatibility complex class II; ICAM-1, intercellular adhesion molecule-1; IL-12p70, interleukin-12p70; IL-10, interleukin-10; TGF-β, transforming growth factor-β; IL-4, interleukin-4.

TABLE 16-1
SOME PHOTOSENSITIVE DISEASES

Actinic keratosis	Solar urticaria
Basal cell carcinoma	Squamous cell carcinoma
Cutaneous lupus erythematosus	Systemic lupus erythematosus
Dermatomyositis	Vitiligo
Malignant melanoma	Xeroderma pigmentosum
Porphyria cutanea tarda	

TABLE 16-2
SOME PHOTOSENSITIZING AGENTS

Antibiotics	Sulfonamides
Coal tar derivatives	Tetracyclines
Diuretics	Thiazides
Oral contraceptives	Tranquilizers
Phenothiazines	

TABLE 16-3
SOME PHOTOPROTECTIVE AGENTS

Aminobenzoic acid (PABA)	Oxybenzone
Avobenzone	Padimate O
Cinoxate	Sulisobenzone
Dioxybenzone	Titanium dioxide
Ecamsule	Zinc oxide
Homosalate	

TABLE 16-4
SOME PHOTOTOXIC AGENTS

Coal tar derivatives	Phenothiazines
Fluoroquinolones	Psoralens
Furocoumarins	Sulfonamides
Nalidixic acid	Tetracyclines
Oral contraceptives	Thiazides
Oxytetracycline	

TABLE 16-5
SOME PHOTOALLERGENS

Antihistamines	Oxybenzone
Benzocaine	Padimate O
Chlorpromazine	Para-aminobenzoic acid (PABA)
Dioxybenzone	Phenothiazines
Ethylenediamine	Sulfonamides
Fragrances	Sulisobenzone
Furocoumarins	Tetracyclines
Griseofulvin	Thiazides
Hydrochlorothiazide	Tranquilizers
Ketoprofen	

TABLE 16-6
SOME PHOTOPROTECTIVE AGENTS

Aminobenzoic acid (PABA)	Oxybenzone
Avobenzone	Padimate O
Cinoxate	Sulisobenzone
Dioxybenzone	Titanium dioxide
Ecamsule	Zinc oxide
Homosalate	

TABLE 16-7
SOME PHOTOTOXIC AGENTS

Coal tar derivatives	Phenothiazines
Fluoroquinolones	Psoralens
Furocoumarins	Sulfonamides
Nalidixic acid	Tetracyclines
Oral contraceptives	Thiazides
Oxytetracycline	

TABLE 16-8
SOME PHOTOALLERGENS

Antihistamines	Oxybenzone
Benzocaine	Padimate O
Chlorpromazine	Para-aminobenzoic acid (PABA)
Dioxybenzone	Phenothiazines
Ethylenediamine	Sulfonamides
Fragrances	Sulisobenzone
Furocoumarins	Tetracyclines
Griseofulvin	Thiazides
Hydrochlorothiazide	Tranquilizers
Ketoprofen

Sensitivity

Skin changes due to other physical and chemical factors

Sensitivity is the ability of a test to correctly identify those with the disease. It is the proportion of true positives that are correctly identified by the test. It is calculated as the number of true positives divided by the sum of the number of true positives and false negatives. It describes how well the test recognizes positive results. If all patients with the disease always test positive, the test has a high degree of sensitivity. Tests with a high sensitivity rarely miss the presence of disease.

Sensitivity is the ability of a test to correctly identify those with the disease. It is the proportion of true positives that are correctly identified by the test. It is calculated as the number of true positives divided by the sum of the number of true positives and false negatives. It describes how well the test recognizes positive results. If all patients with the disease always test positive, the test has a high degree of sensitivity. Tests with a high sensitivity rarely miss the presence of disease.

Specificity

Specificity is the ability of a test to correctly identify those without the disease. It is the proportion of true negatives that are correctly identified by the test. It is calculated as the number of true negatives divided by the sum of the number of true negatives and false positives. It describes how well the test recognizes negative results. If all patients without the disease always test negative, the test has a high degree of specificity. Tests with a high specificity rarely misdiagnose the presence of disease.

Specificity is the ability of a test to correctly identify those without the disease. It is the proportion of true negatives that are correctly identified by the test. It is calculated as the number of true negatives divided by the sum of the number of true negatives and false positives. It describes how well the test recognizes negative results. If all patients without the disease always test negative, the test has a high degree of specificity. Tests with a high specificity rarely misdiagnose the presence of disease.

Positive predictive value

Positive predictive value is the probability that a positive test result is correct. It is calculated as the number of true positives divided by the sum of the number of true positives and false positives. It describes how well the test predicts the presence of disease. If all patients with the disease always test positive, the test has a high degree of positive predictive value. Tests with a high positive predictive value rarely misdiagnose the presence of disease.

Positive predictive value is the probability that a positive test result is correct. It is calculated as the number of true positives divided by the sum of the number of true positives and false positives. It describes how well the test predicts the presence of disease. If all patients with the disease always test positive, the test has a high degree of positive predictive value. Tests with a high positive predictive value rarely misdiagnose the presence of disease.

Negative predictive value

Negative predictive value is the probability that a negative test result is correct. It is calculated as the number of true negatives divided by the sum of the number of true negatives and false negatives. It describes how well the test predicts the absence of disease. If all patients without the disease always test negative, the test has a high degree of negative predictive value. Tests with a high negative predictive value rarely misdiagnose the absence of disease.

Negative predictive value is the probability that a negative test result is correct. It is calculated as the number of true negatives divided by the sum of the number of true negatives and false negatives. It describes how well the test predicts the absence of disease. If all patients without the disease always test negative, the test has a high degree of negative predictive value. Tests with a high negative predictive value rarely misdiagnose the absence of disease.

Likelihood ratio

Likelihood ratio is the probability that a positive test result is correct. It is calculated as the number of true positives divided by the sum of the number of true positives and false positives. It describes how well the test predicts the presence of disease. If all patients with the disease always test positive, the test has a high degree of likelihood ratio. Tests with a high likelihood ratio rarely misdiagnose the presence of disease.

Likelihood ratio is the probability that a positive test result is correct. It is calculated as the number of true positives divided by the sum of the number of true positives and false positives. It describes how well the test predicts the presence of disease. If all patients with the disease always test positive, the test has a high degree of likelihood ratio. Tests with a high likelihood ratio rarely misdiagnose the presence of disease.

Pre-test probability

Pre-test probability is the probability that a positive test result is correct. It is calculated as the number of true positives divided by the sum of the number of true positives and false positives. It describes how well the test predicts the presence of disease. If all patients with the disease always test positive, the test has a high degree of pre-test probability. Tests with a high pre-test probability rarely misdiagnose the presence of disease.

Pre-test probability is the probability that a positive test result is correct. It is calculated as the number of true positives divided by the sum of the number of true positives and false positives. It describes how well the test predicts the presence of disease. If all patients with the disease always test positive, the test has a high degree of pre-test probability. Tests with a high pre-test probability rarely misdiagnose the presence of disease.

Post-test probability

Post-test probability is the probability that a positive test result is correct. It is calculated as the number of true positives divided by the sum of the number of true positives and false positives. It describes how well the test predicts the presence of disease. If all patients with the disease always test positive, the test has a high degree of post-test probability. Tests with a high post-test probability rarely misdiagnose the presence of disease.

Post-test probability is the probability that a positive test result is correct. It is calculated as the number of true positives divided by the sum of the number of true positives and false positives. It describes how well the test predicts the presence of disease. If all patients with the disease always test positive, the test has a high degree of post-test probability. Tests with a high post-test probability rarely misdiagnose the presence of disease.

Pre-test odds

Pre-test odds is the probability that a positive test result is correct. It is calculated as the number of true positives divided by the sum of the number of true positives and false positives. It describes how well the test predicts the presence of disease. If all patients with the disease always test positive, the test has a high degree of pre-test odds. Tests with a high pre-test odds rarely misdiagnose the presence of disease.

Pre-test odds is the probability that a positive test result is correct. It is calculated as the number of true positives divided by the sum of the number of true positives and false positives. It describes how well the test predicts the presence of disease. If all patients with the disease always test positive, the test has a high degree of pre-test odds. Tests with a high pre-test odds rarely misdiagnose the presence of disease.

Post-test odds

Post-test odds is the probability that a positive test result is correct. It is calculated as the number of true positives divided by the sum of the number of true positives and false positives. It describes how well the test predicts the presence of disease. If all patients with the disease always test positive, the test has a high degree of post-test odds. Tests with a high post-test odds rarely misdiagnose the presence of disease.

Post-test odds is the probability that a positive test result is correct. It is calculated as the number of true positives divided by the sum of the number of true positives and false positives. It describes how well the test predicts the presence of disease. If all patients with the disease always test positive, the test has a high degree of post-test odds. Tests with a high post-test odds

Radiation Dermatitis

Radiation dermatitis is a common complication of radiotherapy. Acute radiation dermatitis usually occurs during the second or third week of treatment and is characterized by erythema, dry desquamation, and moist desquamation. Chronic radiation dermatitis may occur months to years after treatment and is characterized by telangiectasia, fibrosis, and atrophy.

Table 18.1 Neurocutaneous syndromes

Syndrome	Inheritance	Gene	Locus	Protein
Neurofibromatosis 1	AD	*NF1*	17q11.2	Neurofibromin
Neurofibromatosis 2	AD	*NF2*	22q12.2	Merlin
Tuberous sclerosis	AD	*TSC1*	9q34	Hamartin
		TSC2	16p13.3	Tuberin
Ataxia telangiectasia	AR	*ATM*	11q22.3	ATM
Xeroderma pigmentosum	AR	*XPA*	9q22.3	XPA
		XPB	2q21	XPB
		XPC	3p25	XPC
		XPD	19q13.3	XPD
		XPE	11p12	XPE
		XPF	16p13.3	XPF
		XPG	13q33	XPG
Cockayne syndrome	AR	*CSA*	5q12	CSA
		CSB	10q11	CSB
Trichothiodystrophy	AR	*XPB*	2q21	XPB
		XPD	19q13.3	XPD
		TTDA	7q21	TTDA
Bloom syndrome	AR	*BLM*	15q26.1	BLM
Rothmund–Thomson syndrome	AR	*RECQL4*	8q24.3	RECQL4
Dyskeratosis congenita	XR	*DKC1*	Xq28	Dyskerin
	AD	*TERC*	3q26.2	Telomerase RNA
	AR	*TERT*	5p15.33	Telomerase reverse transcriptase
Hereditary hemorrhagic telangiectasia	AD	*ENG*	9q34.11	Endoglin
		ACVRL1	12q13.13	ALK1
Ataxia telangiectasia–like disorder	AR	*MRE11A*	11q21	MRE11A
Nijmegen breakage syndrome	AR	*NBS1*	8q21	Nibrin
Ataxia telangiectasia–like disorder	AR	*RAD50*	5q31	RAD50

Introduction

Skin signs of physical abuse are common and are frequently the first indication that a child is being abused. Skin signs may be the only evidence of abuse, or they may be associated with other signs of abuse, such as fractures or head injuries. Skin signs may be accidental, self-inflicted, or inflicted by another person. Skin signs may be acute or chronic. Skin signs may be single or multiple. Skin signs may be localized or generalized. Skin signs may be symmetrical or asymmetrical. Skin signs may be linear or irregular. Skin signs may be superficial or deep. Skin signs may be painful or painless. Skin signs may be pruritic or nonpruritic. Skin signs may be erythematous or nonerythematous. Skin signs may be edematous or nonedematous. Skin signs may be vesicular or nonvesicular. Skin signs may be bullous or nonbullous. Skin signs may be pustular or nonpustular. Skin signs may be crusted or noncrusted. Skin signs may be scaly or nonscaly. Skin signs may be hyperpigmented or hypopigmented. Skin signs may be depigmented or repigmented. Skin signs may be scarred or unscarred. Skin signs may be atrophic or nonatrophic. Skin signs may be hypertrophic or nonhypertrophic. Skin signs may be keloidal or nonkeloidal. Skin signs may be calcified or noncalcified. Skin signs may be ossified or nonossified. Skin signs may be cartilaginous or noncartilaginous. Skin signs may be fibrous or nonfibrous. Skin signs may be adipose or nonadipose. Skin signs may be muscular or nonmuscular. Skin signs may be vascular or nonvascular. Skin signs may be neural or nonneural. Skin signs may be glandular or nonglandular. Skin signs may be mucosal or nonmucosal. Skin signs may be conjunctival or nonconjunctival. Skin signs may be oral or nonoral. Skin signs may be genital or nongenital. Skin signs may be anal or nonanal. Skin signs may be perianal or nonperianal. Skin signs may be perineal or nonperineal. Skin signs may be inguinal or noninguinal. Skin signs may be axillary or nonaxillary. Skin signs may be cervical or noncervical. Skin signs may be facial or nonfacial. Skin signs may be scalp or nonscalp. Skin signs may be hand or nonhand. Skin signs may be foot or nonfoot. Skin signs may be trunk or nontrunk. Skin signs may be extremity or nonextremity. Skin signs may be joint or nonjoint. Skin signs may be bone or nonbone. Skin signs may be muscle or nonmuscle. Skin signs may be tendon or nontendon. Skin signs may be ligament or nonligament. Skin signs may be cartilage or noncartilage. Skin signs may be fat or nonfat. Skin signs may be connective tissue or nonconnective tissue. Skin signs may be epithelial or nonepithelial. Skin signs may be mesothelial or nonmesothelial. Skin signs may be endothelial or nonendothelial. Skin signs may be neuroectodermal or nonneuroectodermal. Skin signs may be mesenchymal or nonmesenchymal. Skin signs may be ectodermal or nonectodermal. Skin signs may be endodermal or nonendodermal. Skin signs may be mesodermal or nonmesodermal. Skin signs may be neural crest or nonneural crest. Skin signs may be placodal or nonplacodal. Skin signs may be somitic or nonsomitic. Skin signs may be notochordal or nonnotochordal. Skin signs may be pharyngeal or nonpharyngeal. Skin signs may be branchial or nonbranchial. Skin signs may be pharyngeal pouch or nonpharyngeal pouch. Skin signs may be branchial cleft or nonbranchial cleft. Skin signs may be pharyngeal arch or nonpharyngeal arch. Skin signs may be branchial arch or nonbranchial arch. Skin signs may be pharyngeal groove or nonpharyngeal groove. Skin signs may be branchial groove or nonbranchial groove. Skin signs may be pharyngeal membrane or nonpharyngeal membrane. Skin signs may be branchial membrane or nonbranchial membrane. Skin signs may be pharyngeal septum or nonpharyngeal septum. Skin signs may be branchial septum or nonbranchial septum. Skin signs may be pharyngeal cleft or nonpharyngeal cleft. Skin signs may be branchial cleft or nonbranchial cleft. Skin signs may be pharyngeal pouch or nonpharyngeal pouch. Skin signs may be branchial pouch or nonbranchial pouch. Skin signs may be pharyngeal arch or nonpharyngeal arch. Skin signs may be branchial arch or nonbranchial arch. Skin signs may be pharyngeal groove or nonpharyngeal groove. Skin signs may be branchial groove or nonbranchial groove. Skin signs may be pharyngeal membrane or nonpharyngeal membrane. Skin signs may be branchial membrane or nonbranchial membrane. Skin signs may be pharyngeal septum or nonpharyngeal septum. Skin signs may be branchial septum or nonbranchial septum.

Bruises

Bruises are the most common skin sign of physical abuse. Bruises are caused by the rupture of blood vessels in the skin. Bruises may be caused by a variety of mechanisms, including blunt force trauma, pinching, and shaking. Bruises may be accidental, self-inflicted, or inflicted by another person. Bruises may be acute or chronic. Bruises may be single or multiple. Bruises may be localized or generalized. Bruises may be symmetrical or asymmetrical. Bruises may be linear or irregular. Bruises may be superficial or deep. Bruises may be painful or painless. Bruises may be pruritic or nonpruritic. Bruises may be erythematous or nonerythematous. Bruises may be edematous or nonedematous. Bruises may be vesicular or nonvesicular. Bruises may be bullous or nonbullous. Bruises may be pustular or nonpustular. Bruises may be crusted or noncrusted. Bruises may be scaly or nonscaly. Bruises may be hyperpigmented or hypopigmented. Bruises may be depigmented or repigmented. Bruises may be scarred or unscarred. Bruises may be atrophic or nonatrophic. Bruises may be hypertrophic or nonhypertrophic. Bruises may be keloidal or nonkeloidal. Bruises may be calcified or noncalcified. Bruises may be ossified or nonossified. Bruises may be cartilaginous or noncartilaginous. Bruises may be fibrous or nonfibrous. Bruises may be adipose or nonadipose. Bruises may be muscular or nonmuscular. Bruises may be vascular or nonvascular. Bruises may be neural or nonneural. Bruises may be glandular or nonglandular. Bruises may be mucosal or nonmucosal. Bruises may be conjunctival or nonconjunctival. Bruises may be oral or nonoral. Bruises may be genital or nongenital. Bruises may be anal or nonanal. Bruises may be perianal or nonperianal. Bruises may be perineal or nonperineal. Bruises may be inguinal or noninguinal. Bruises may be axillary or nonaxillary. Bruises may be cervical or noncervical. Bruises may be facial or nonfacial. Bruises may be scalp or nonscalp. Bruises may be hand or nonhand. Bruises may be foot or nonfoot. Bruises may be trunk or nontrunk. Bruises may be extremity or nonextremity. Bruises may be joint or nonjoint. Bruises may be bone or nonbone. Bruises may be muscle or nonmuscle. Bruises may be tendon or nontendon. Bruises may be ligament or nonligament. Bruises may be cartilage or noncartilage. Bruises may be fat or nonfat. Bruises may be connective tissue or nonconnective tissue. Bruises may be epithelial or nonepithelial. Bruises may be mesothelial or nonmesothelial. Bruises may be endothelial or nonendothelial. Bruises may be neuroectodermal or nonneuroectodermal. Bruises may be mesenchymal or nonmesenchymal. Bruises may be ectodermal or nonectodermal. Bruises may be endodermal or nonendodermal. Bruises may be mesodermal or nonmesodermal. Bruises may be neural crest or nonneural crest. Bruises may be placodal or nonplacodal. Bruises may be somitic or nonsomitic. Bruises may be notochordal or nonnotochordal. Bruises may be pharyngeal or nonpharyngeal. Bruises may be branchial or nonbranchial. Bruises may be pharyngeal pouch or nonpharyngeal pouch. Bruises may be branchial cleft or nonbranchial cleft. Bruises may be pharyngeal arch or nonpharyngeal arch. Bruises may be branchial arch or nonbranchial arch. Bruises may be pharyngeal groove or nonpharyngeal groove. Bruises may be branchial groove or nonbranchial groove. Bruises may be pharyngeal membrane or nonpharyngeal membrane. Bruises may be branchial membrane or nonbranchial membrane. Bruises may be pharyngeal septum or nonpharyngeal septum. Bruises may be branchial septum or nonbranchial septum.

Burns

Burns are the second most common skin sign of physical abuse. Burns are caused by the application of heat to the skin. Burns may be caused by a variety of mechanisms, including hot liquids, hot objects, and flames. Burns may be accidental, self-inflicted, or inflicted by another person. Burns may be acute or chronic. Burns may be single or multiple. Burns may be localized or generalized. Burns may be symmetrical or asymmetrical. Burns may be linear or irregular. Burns may be superficial or deep. Burns may be painful or painless. Burns may be pruritic or nonpruritic. Burns may be erythematous or nonerythematous. Burns may be edematous or nonedematous. Burns may be vesicular or nonvesicular. Burns may be bullous or nonbullous. Burns may be pustular or nonpustular. Burns may be crusted or noncrusted. Burns may be scaly or nonscaly. Burns may be hyperpigmented or hypopigmented. Burns may be depigmented or repigmented. Burns may be scarred or unscarred. Burns may be atrophic or nonatrophic. Burns may be hypertrophic or nonhypertrophic. Burns may be keloidal or nonkeloidal. Burns may be calcified or noncalcified. Burns may be ossified or nonossified. Burns may be cartilaginous or noncartilaginous. Burns may be fibrous or nonfibrous. Burns may be adipose or nonadipose. Burns may be muscular or nonmuscular. Burns may be vascular or nonvascular. Burns may be neural or nonneural. Burns may be glandular or nonglandular. Burns may be mucosal or nonmucosal. Burns may be conjunctival or nonconjunctival. Burns may be oral or nonoral. Burns may be genital or nongenital. Burns may be anal or nonanal. Burns may be perianal or nonperianal. Burns may be perineal or nonperineal. Burns may be inguinal or noninguinal. Burns may be axillary or nonaxillary. Burns may be cervical or noncervical. Burns may be facial or nonfacial. Burns may be scalp or nonscalp. Burns may be hand or nonhand. Burns may be foot or nonfoot. Burns may be trunk or nontrunk. Burns may be extremity or nonextremity. Burns may be joint or nonjoint. Burns may be bone or nonbone. Burns may be muscle or nonmuscle. Burns may be tendon or nontendon. Burns may be ligament or nonligament. Burns may be cartilage or noncartilage. Burns may be fat or nonfat. Burns may be connective tissue or nonconnective tissue. Burns may be epithelial or nonepithelial. Burns may be mesothelial or nonmesothelial. Burns may be endothelial or nonendothelial. Burns may be neuroectodermal or nonneuroectodermal. Burns may be mesenchymal or nonmesenchymal. Burns may be ectodermal or nonectodermal. Burns may be endodermal or nonendodermal. Burns may be mesodermal or nonmesodermal. Burns may be neural crest or nonneural crest. Burns may be placodal or nonplacodal. Burns may be somitic or nonsomitic. Burns may be notochordal or nonnotochordal. Burns may be pharyngeal or nonpharyngeal. Burns may be branchial or nonbranchial. Burns may be pharyngeal pouch or nonpharyngeal pouch. Burns may be branchial cleft or nonbranchial cleft. Burns may be pharyngeal arch or nonpharyngeal arch. Burns may be branchial arch or nonbranchial arch. Burns may be pharyngeal groove or nonpharyngeal groove. Burns may be branchial groove or nonbranchial groove. Burns may be pharyngeal membrane or nonpharyngeal membrane. Burns may be branchial membrane or nonbranchial membrane. Burns may be pharyngeal septum or nonpharyngeal septum. Burns may be branchial septum or nonbranchial septum.

Fractures

Fractures are the third most common skin sign of physical abuse. Fractures are caused by the application of force to the bone. Fractures may be caused by a variety of mechanisms, including blunt force trauma, twisting, and shaking. Fractures may be accidental, self-inflicted, or inflicted by another person. Fractures may be acute or chronic. Fractures may be single or multiple. Fractures may be localized or generalized. Fractures may be symmetrical or asymmetrical. Fractures may be linear or irregular. Fractures may be superficial or deep. Fractures may be painful or painless. Fractures may be pruritic or nonpruritic. Fractures may be erythematous or nonerythematous. Fractures may be edematous or nonedematous. Fractures may be vesicular or nonvesicular. Fractures may be bullous or nonbullous. Fractures may be pustular or nonpustular. Fractures may be crusted or noncrusted. Fractures may be scaly or nonscaly. Fractures may be hyperpigmented or hypopigmented. Fractures may be depigmented or repigmented. Fractures may be scarred or unscarred. Fractures may be atrophic or nonatrophic. Fractures may be hypertrophic or nonhypertrophic. Fractures may be keloidal or nonkeloidal. Fractures may be calcified or noncalcified. Fractures may be ossified or nonossified. Fractures may be cartilaginous or noncartilaginous. Fractures may be fibrous or nonfibrous. Fractures may be adipose or nonadipose. Fractures may be muscular or nonmuscular. Fractures may be vascular or nonvascular. Fractures may be neural or nonneural. Fractures may be glandular or nonglandular. Fractures may be mucosal or nonmucosal. Fractures may be conjunctival or nonconjunctival. Fractures may be oral or nonoral. Fractures may be genital or nongenital. Fractures may be anal or nonanal. Fractures may be perianal or nonperianal. Fractures may be perineal or nonperineal. Fractures may be inguinal or noninguinal. Fractures may be axillary or nonaxillary. Fractures may be cervical or noncervical. Fractures may be facial or nonfacial. Fractures may be scalp or nonscalp. Fractures may be hand or nonhand. Fractures may be foot or nonfoot. Fractures may be trunk or nontrunk. Fractures may be extremity or nonextremity. Fractures may be joint or nonjoint. Fractures may be bone or nonbone. Fractures may be muscle or nonmuscle. Fractures may be tendon or nontendon. Fractures may be ligament or nonligament. Fractures may be cartilage or noncartilage. Fractures may be fat or nonfat. Fractures may be connective tissue or nonconnective tissue. Fractures may be epithelial or nonepithelial. Fractures may be mesothelial or nonmesothelial. Fractures may be endothelial or nonendothelial. Fractures may be neuroectodermal or nonneuroectodermal. Fractures may be mesenchymal or nonmesenchymal. Fractures may be ectodermal or nonectodermal. Fractures may be endodermal or nonendodermal. Fractures may be mesodermal or nonmesodermal. Fractures may be neural crest or nonneural crest. Fractures may be placodal or nonplacodal. Fractures may be somitic or nonsomitic. Fractures may be notochordal or nonnotochordal. Fractures may be pharyngeal or nonpharyngeal. Fractures may be branchial or nonbranchial. Fractures may be pharyngeal pouch or nonpharyngeal pouch. Fractures may be branchial cleft or nonbranchial cleft. Fractures may be pharyngeal arch or nonpharyngeal arch. Fractures may be branchial arch or nonbranchial arch. Fractures may be pharyngeal groove or nonpharyngeal groove. Fractures may be branchial groove or nonbranchial groove. Fractures may be pharyngeal membrane or nonpharyngeal membrane. Fractures may be branchial membrane or nonbranchial membrane. Fractures may be pharyngeal septum or nonpharyngeal septum. Fractures may be branchial septum or nonbranchial septum.

Head Injuries

Head injuries are the fourth most common skin sign of physical abuse. Head injuries are caused by the application of force to the head. Head injuries may be caused by a variety of mechanisms, including blunt force trauma, shaking, and penetrating trauma. Head injuries may be accidental, self-inflicted, or inflicted by another person. Head injuries may be acute or chronic. Head injuries may be single or multiple. Head injuries may be localized or generalized. Head injuries may be symmetrical or asymmetrical. Head injuries may be linear or irregular. Head injuries may be superficial or deep. Head injuries may be painful or painless. Head injuries may be pruritic or nonpruritic. Head injuries may be erythematous or nonerythematous. Head injuries may be edematous or nonedematous. Head injuries may be vesicular or nonvesicular. Head injuries may be bullous or nonbullous. Head injuries may be pustular or nonpustular. Head injuries may be crusted or noncrusted. Head injuries may be scaly or nonscaly. Head injuries may be hyperpigmented or hypopigmented. Head injuries may be depigmented or repigmented. Head injuries may be scarred or unscarred. Head injuries may be atrophic or nonatrophic. Head injuries may be hypertrophic or nonhypertrophic. Head injuries may be keloidal or nonkeloidal. Head injuries may be calcified or noncalcified. Head injuries may be ossified or nonossified. Head injuries may be cartilaginous or noncartilaginous. Head injuries may be fibrous or nonfibrous. Head injuries may be adipose or nonadipose. Head injuries may be muscular or nonmuscular. Head injuries may be vascular or nonvascular. Head injuries may be neural or nonneural. Head injuries may be glandular or nonglandular. Head injuries may be mucosal or nonmucosal. Head injuries may be conjunctival or nonconjunctival. Head injuries may be oral or nonoral. Head injuries may be genital or nongenital. Head injuries may be anal or nonanal. Head injuries may be perianal or nonperianal. Head injuries may be perineal or nonperineal. Head injuries may be inguinal or noninguinal. Head injuries may be axillary or nonaxillary. Head injuries may be cervical or noncervical. Head injuries may be facial or nonfacial. Head injuries may be scalp or nonscalp. Head injuries may be hand or nonhand. Head injuries may be foot or nonfoot. Head injuries may be trunk or nontrunk. Head injuries may be extremity or nonextremity. Head injuries may be joint or nonjoint. Head injuries may be bone or nonbone. Head injuries may be muscle or nonmuscle. Head injuries may be tendon or nontendon. Head injuries may be ligament or nonligament. Head injuries may be cartilage or noncartilage. Head injuries may be fat or nonfat. Head injuries may be connective tissue or nonconnective tissue. Head injuries may be epithelial or nonepithelial. Head injuries may be mesothelial or nonmesothelial. Head injuries may be endothelial or nonendothelial. Head injuries may be neuroectodermal or nonneuroectodermal. Head injuries may be mesenchymal or nonmesenchymal. Head injuries may be ectodermal or nonectodermal. Head injuries may be endodermal or nonendodermal. Head injuries may be mesodermal or nonmesodermal. Head injuries may be neural crest or nonneural crest. Head injuries may be placodal or nonplacodal. Head injuries may be somitic or nonsomitic. Head injuries may be notochordal or nonnotochordal. Head injuries may be pharyngeal or nonpharyngeal. Head injuries may be branchial or nonbranchial. Head injuries may be pharyngeal pouch or nonpharyngeal pouch. Head injuries may be branchial cleft or nonbranchial cleft. Head injuries may be pharyngeal arch or nonpharyngeal arch. Head injuries may be branchial arch or nonbranchial arch. Head injuries may be pharyngeal groove or nonpharyngeal groove. Head injuries may be branchial groove or nonbranchial groove. Head injuries may be pharyngeal membrane or nonpharyngeal membrane. Head injuries may be branchial membrane or nonbranchial membrane. Head injuries may be pharyngeal septum or nonpharyngeal septum. Head injuries may be branchial septum or nonbranchial septum.

Abdominal Injuries

Abdominal injuries are the fifth most common skin sign of physical abuse. Abdominal injuries are caused by the application of force to the abdomen. Abdominal injuries may be caused by a variety of mechanisms, including blunt force trauma, shaking, and penetrating trauma. Abdominal injuries may be accidental, self-inflicted, or inflicted by another person. Abdominal injuries may be acute or chronic. Abdominal injuries may be single or multiple. Abdominal injuries may be localized or generalized. Abdominal injuries may be symmetrical or asymmetrical. Abdominal injuries may be linear or irregular. Abdominal injuries may be superficial or deep. Abdominal injuries may be painful or painless. Abdominal injuries may be pruritic or nonpruritic. Abdominal injuries may be erythematous or nonerythematous. Abdominal injuries may be edematous or nonedematous. Abdominal injuries may be vesicular or nonvesicular. Abdominal injuries may be bullous or nonbullous. Abdominal injuries may be pustular or nonpustular. Abdominal injuries may be crusted or noncrusted. Abdominal injuries may be scaly or nonscaly. Abdominal injuries may be hyperpigmented or hypopigmented. Abdominal injuries may be depigmented or repigmented. Abdominal injuries may be scarred or unscarred. Abdominal injuries may be atrophic or nonatrophic. Abdominal injuries may be hypertrophic or nonhypertrophic. Abdominal injuries may be keloidal or nonkeloidal. Abdominal injuries may be calcified or noncalcified. Abdominal injuries may be ossified or nonossified. Abdominal injuries may be cartilaginous or noncartilaginous. Abdominal injuries may be fibrous or nonfibrous. Abdominal injuries may be adipose or nonadipose. Abdominal injuries may be muscular or nonmuscular. Abdominal injuries may be vascular or nonvascular. Abdominal injuries may be neural or nonneural. Abdominal injuries may be glandular or nonglandular. Abdominal injuries may be mucosal or nonmucosal. Abdominal injuries may be conjunctival or nonconjunctival. Abdominal injuries may be oral or nonoral. Abdominal injuries may be genital or nongenital. Abdominal injuries may be anal or nonanal. Abdominal injuries may be perianal or nonperianal. Abdominal injuries may be perineal or nonperineal. Abdominal injuries may be inguinal or noninguinal. Abdominal injuries may be axillary or nonaxillary. Abdominal injuries may be cervical or noncervical. Abdominal injuries may be facial or nonfacial. Abdominal injuries may be scalp or nonscalp. Abdominal injuries may be hand or nonhand. Abdominal injuries may be foot or nonfoot. Abdominal injuries may be trunk or nontrunk. Abdominal injuries may be extremity or nonextremity. Abdominal injuries may be joint or nonjoint. Abdominal injuries may be bone or nonbone. Abdominal injuries may be muscle or nonmuscle. Abdominal injuries may be tendon or nontendon. Abdominal injuries may be ligament or nonligament. Abdominal injuries may be cartilage or noncartilage. Abdominal injuries may be fat or nonfat. Abdominal injuries may be connective tissue or nonconnective tissue. Abdominal injuries may be epithelial or nonepithelial. Abdominal injuries may be mesothelial or nonmesothelial. Abdominal injuries may be endothelial or nonendothelial. Abdominal injuries may be neuroectodermal or nonneuroectodermal. Abdominal injuries may be mesenchymal or nonmesenchymal. Abdominal injuries may be ectodermal or nonectodermal. Abdominal injuries may be endodermal or nonendodermal. Abdominal injuries may be mesodermal or nonmesodermal. Abdominal injuries may be neural crest or nonneural crest. Abdominal injuries may be placodal or nonplacodal. Abdominal injuries may be somitic or nonsomitic. Abdominal injuries may be notochordal or nonnotochordal. Abdominal injuries may be pharyngeal or nonpharyngeal. Abdominal injuries may be branchial or nonbranchial. Abdominal injuries may be pharyngeal pouch or nonpharyngeal pouch. Abdominal injuries may be branchial cleft or nonbranchial cleft. Abdominal injuries may be pharyngeal arch or nonpharyngeal arch. Abdominal injuries may be branchial arch or nonbranchial arch. Abdominal injuries may be pharyngeal groove or nonpharyngeal groove. Abdominal injuries may be branchial groove or nonbranchial groove. Abdominal injuries may be pharyngeal membrane or nonpharyngeal membrane. Abdominal injuries may be branchial membrane or nonbranchial membrane. Abdominal injuries may be pharyngeal septum or nonpharyngeal septum. Abdominal injuries may be branchial septum or nonbranchial septum.

Genital Injuries

Genital injuries are the sixth most common skin sign of physical abuse. Genital injuries are caused by the application of force to the genitals. Genital injuries may be caused by a variety of mechanisms, including blunt force trauma, shaking, and penetrating trauma. Genital injuries may be accidental, self-inflicted, or inflicted by another person. Genital injuries may be acute or chronic. Genital injuries may be single or multiple. Genital injuries may be localized or generalized. Genital injuries may be symmetrical or asymmetrical. Genital injuries may be linear or irregular. Genital injuries may be superficial or deep. Genital injuries may be painful or painless. Genital injuries may be pruritic or nonpruritic. Genital injuries may be erythematous or nonerythematous. Genital injuries may be edematous or nonedematous. Genital injuries may be vesicular or nonvesicular. Genital injuries may be bullous or nonbullous. Genital injuries may be pustular or nonpustular. Genital injuries may be crusted or noncrusted. Genital injuries may be scaly or nonscaly. Genital injuries may be hyperpigmented or hypopigmented. Genital injuries may be depigmented or repigmented. Genital injuries may be scarred or unscarred. Genital injuries may be atrophic or nonatrophic. Genital injuries may be hypertrophic or nonhypertrophic. Genital injuries may be keloidal or nonkeloidal. Genital injuries may be calcified or noncalcified. Genital injuries may be ossified or nonossified. Genital injuries may be cartilaginous or noncartilaginous. Genital injuries may be fibrous or nonfibrous. Genital injuries may be adipose or nonadipose. Genital injuries may be muscular or nonmuscular. Genital injuries may be vascular or nonvascular. Genital injuries may be neural or nonneural. Genital injuries may be glandular or nonglandular. Genital injuries may be mucosal or nonmucosal. Genital injuries may be conjunctival or nonconjunctival. Genital injuries may be oral or nonoral. Genital injuries may be genital or nongenital. Genital injuries may be anal or nonanal. Genital injuries may be perianal or nonperianal. Genital injuries may be perineal or nonperineal. Genital injuries may be inguinal or noninguinal. Genital injuries may be axillary or nonaxillary. Genital injuries may be cervical or noncervical. Genital injuries may be facial or nonfacial. Genital injuries may be scalp or nonscalp. Genital injuries may be hand or nonhand. Genital injuries may be foot or nonfoot. Genital injuries may be trunk or nontrunk. Genital injuries may be extremity or nonextremity. Genital injuries may be joint or nonjoint. Genital injuries may be bone or nonbone. Genital injuries may be muscle or nonmuscle. Genital injuries may be tendon or nontendon. Genital injuries may be ligament or nonligament. Genital injuries may be cartilage or noncartilage. Genital injuries may be fat or nonfat. Genital injuries may be connective tissue or nonconnective tissue. Genital injuries may be epithelial or nonepithelial. Genital injuries may be mesothelial or nonmesothelial. Genital injuries may be endothelial or nonendothelial. Genital injuries may be neuroectodermal or nonneuroectodermal. Genital injuries may be mesenchymal or nonmesenchymal. Genital injuries may be ectodermal or nonectodermal. Genital injuries may be endodermal or nonendodermal. Genital injuries may be mesodermal or nonmesodermal. Genital injuries may be neural crest or nonneural crest. Genital injuries may be placodal or nonplacodal. Genital injuries may be somitic or nonsomitic. Genital injuries may be notochordal or nonnotochordal. Genital injuries may be pharyngeal or nonpharyngeal. Genital injuries may be branchial or nonbranchial. Genital injuries may be pharyngeal pouch or nonpharyngeal pouch. Genital injuries may be branchial cleft or nonbranchial cleft. Genital injuries may be pharyngeal arch or nonpharyngeal arch. Genital injuries may be branchial arch or nonbranchial arch. Genital injuries may be pharyngeal groove or nonpharyngeal groove. Genital injuries may be branchial groove or nonbranchial groove. Genital injuries may be pharyngeal membrane or nonpharyngeal membrane. Genital injuries may be branchial membrane or nonbranchial membrane. Genital injuries may be pharyngeal septum or nonpharyngeal septum. Genital injuries may be branchial septum or nonbranchial septum.

Anal Injuries

Anal injuries are the seventh most common skin sign of physical abuse. Anal injuries are caused by the application of force to the anus. Anal injuries may be caused by a variety of mechanisms, including blunt force trauma, shaking, and penetrating trauma. Anal injuries may be accidental, self-inflicted, or inflicted by another person. Anal injuries may be acute or chronic. Anal injuries may be single or multiple. Anal injuries may be localized or generalized. Anal injuries may be symmetrical or asymmetrical. Anal injuries may be linear or irregular. Anal injuries may be superficial or deep. Anal injuries may be painful or painless. Anal injuries may be pruritic or nonpruritic. Anal injuries may be erythematous or nonerythematous. Anal injuries may be edematous or nonedematous. Anal injuries may be vesicular or nonvesicular. Anal injuries may be bullous or nonbullous. Anal injuries may be pustular or nonpustular. Anal injuries may be crusted or noncrusted. Anal injuries may be scaly or nonscaly. Anal injuries may be hyperpigmented or hypopigmented. Anal injuries may be depigmented or repigmented. Anal injuries may be scarred or unscarred. Anal injuries may be atrophic or nonatrophic. Anal injuries may be hypertrophic or nonhypertrophic. Anal injuries may be keloidal or nonkeloidal. Anal injuries may be calcified or noncalcified. Anal injuries may be ossified or nonossified. Anal injuries may be cartilaginous or noncartilaginous. Anal injuries may be fibrous or nonfibrous. Anal injuries may be adipose or nonadipose. Anal injuries may be muscular or nonmuscular. Anal injuries may be vascular or nonvascular. Anal injuries may be neural or nonneural. Anal injuries may be glandular or nonglandular. Anal injuries may be mucosal or nonmucosal. Anal injuries may be conjunctival or nonconjunctival. Anal injuries may be oral or nonoral. Anal injuries may be genital or nongenital. Anal injuries may be anal or nonanal. Anal injuries may be perianal or nonperianal. Anal injuries may be perineal or nonperineal. Anal injuries may be inguinal or noninguinal. Anal injuries may be axillary or nonaxillary. Anal injuries may be cervical or noncervical. Anal injuries may be facial or nonfacial. Anal injuries may be scalp or nonscalp. Anal injuries may be hand or nonhand. Anal injuries may be foot or nonfoot. Anal injuries may be trunk or nontrunk. Anal injuries may be extremity or nonextremity. Anal injuries may be joint or nonjoint. Anal injuries may be bone or nonbone. Anal injuries may be muscle or nonmuscle. Anal injuries may be tendon or nontendon. Anal injuries may be ligament or nonligament. Anal injuries may be cartilage or noncartilage. Anal injuries may be fat or nonfat. Anal injuries may be connective tissue or nonconnective tissue. Anal injuries may be epithelial or nonepithelial. Anal injuries may be mesothelial or nonmesothelial. Anal injuries may be endothelial or nonendothelial. Anal injuries may be neuroectodermal or nonneuroectodermal. Anal injuries may be mesenchymal or nonmesenchymal. Anal injuries may be ectodermal or nonectodermal. Anal injuries may be endodermal or nonendodermal. Anal injuries may be mesodermal or nonmesodermal. Anal injuries may be neural crest or nonneural crest. Anal injuries may be placodal or nonplacodal. Anal injuries may be somitic or nonsomitic. Anal injuries may be notochordal or nonnotochordal. Anal injuries may be pharyngeal or nonpharyngeal. Anal injuries may be branchial or nonbranchial. Anal injuries may be pharyngeal pouch or nonpharyngeal pouch. Anal injuries may be branchial cleft or nonbranchial cleft. Anal injuries may be pharyngeal arch or nonpharyngeal arch. Anal injuries may be branchial arch or nonbranchial arch. Anal injuries may be pharyngeal groove or nonpharyngeal groove. Anal injuries may be branchial groove or nonbranchial groove. Anal injuries may be pharyngeal membrane or nonpharyngeal membrane. Anal injuries may be branchial membrane or nonbranchial membrane. Anal injuries may be pharyngeal septum or nonpharyngeal septum. Anal injuries may be branchial septum or nonbranchial septum.

Perianal Injuries

Perianal injuries are the eighth most common skin sign of physical abuse. Perianal injuries are caused by the application of force to the perianal area. Perianal injuries may be caused by a variety of mechanisms, including blunt force trauma, shaking, and penetrating trauma. Perianal injuries may be accidental, self-inflicted, or inflicted by another person. Perianal injuries may be acute or chronic. Perianal injuries may be single or multiple. Perianal injuries may be localized or generalized. Perianal injuries may be symmetrical or asymmetrical. Perianal injuries may be linear or irregular. Perianal injuries may be superficial or deep. Perianal injuries may be painful or painless. Perianal injuries may be pruritic or nonpruritic. Perianal injuries may be erythematous or nonerythematous. Perianal injuries may be edematous or nonedematous. Perianal injuries may be vesicular or nonvesicular. Perianal injuries may be bullous or nonbullous. Perianal injuries may be pustular or nonpustular. Perianal injuries may be crusted or noncrusted. Perianal injuries may be scaly or nonscaly. Perianal injuries may be hyperpigmented or hypopigmented. Perianal injuries may be depigmented or repigmented. Perianal injuries may be scarred or unscarred. Perianal injuries may be atrophic or nonatrophic. Perianal injuries may be hypertrophic or nonhypertrophic. Perianal injuries may be keloidal or nonkeloidal. Perianal injuries may be calcified or noncalcified. Perianal injuries may be ossified or nonossified. Perianal injuries may be cartilaginous or noncartilaginous. Perianal injuries may be fibrous or nonfibrous. Perianal injuries may be adipose or nonadipose. Perianal injuries may be muscular or nonmuscular. Perianal injuries may be vascular or nonvascular. Perianal injuries may be neural or nonneural. Perianal injuries may be glandular or nonglandular. Perianal injuries may be mucosal or nonmucosal. Perianal injuries may be conjunctival or nonconjunctival. Perianal injuries may be oral or nonoral. Perianal injuries may be genital or nongenital. Perianal injuries may be anal or nonanal. Perianal injuries may be perianal or nonperianal. Perianal injuries may be perineal or nonperineal. Perianal injuries may be inguinal or noninguinal. Perianal injuries may be axillary or nonaxillary. Perianal injuries may be cervical or noncervical. Perianal injuries may be facial or nonfacial. Perianal injuries may be scalp or nonscalp. Perianal injuries may be hand or nonhand. Perianal injuries may be foot or nonfoot. Perianal injuries may be trunk or nontrunk. Perianal injuries may be extremity or nonextremity. Perianal injuries may be joint or nonjoint. Perianal injuries may be bone or nonbone. Perianal injuries may be muscle or nonmuscle. Perianal injuries may be tendon or nontendon. Perianal injuries may be ligament or nonligament. Perianal injuries may be cartilage or noncartilage. Perianal injuries may be fat or nonfat. Perianal injuries may be connective tissue or nonconnective tissue. Perianal injuries may be epithelial or nonepithelial. Perianal injuries may be mesothelial or nonmesothelial. Perianal injuries may be endothelial or nonendothelial. Perianal injuries may be neuroectodermal or nonneuroectodermal. Perianal injuries may be mesenchymal or nonmesenchymal. Perianal injuries may be ectodermal or nonectodermal. Perianal injuries may be endodermal or nonendodermal. Perianal injuries may be mesodermal or nonmesodermal. Perianal injuries may be neural crest or nonneural crest. Perianal injuries may be placodal or nonplacodal. Perianal injuries may be somitic or nonsomitic. Perianal injuries may be notochordal or nonnotochordal. Perianal injuries may be pharyngeal or nonpharyngeal. Perianal injuries may be branchial or nonbranchial. Perianal injuries may be pharyngeal pouch or nonpharyngeal pouch. Perianal injuries may be branchial cleft or nonbranchial cleft. Perianal injuries may be pharyngeal arch or nonpharyngeal arch. Perianal injuries may be branchial arch or nonbranchial arch. Perianal injuries may be pharyngeal groove or nonpharyngeal groove. Perianal injuries may be branchial groove or nonbranchial groove. Perianal injuries may be pharyngeal membrane or nonpharyngeal membrane. Perianal injuries may be branchial membrane or nonbranchial membrane. Perianal injuries may be pharyngeal septum or nonpharyngeal septum. Perianal injuries may be branchial septum or nonbranchial septum.

Perineal Injuries

Perineal injuries are the ninth most common skin sign of physical abuse. Perineal injuries are caused by the application of force to the perineal area. Perineal injuries may be caused by a variety of mechanisms, including blunt force trauma, shaking, and penetrating trauma. Perineal injuries may be accidental, self-inflicted, or inflicted by another person. Perineal injuries may be acute or chronic. Perineal injuries may be single or multiple. Perineal injuries may be localized or generalized. Perineal injuries may be symmetrical or asymmetrical. Perineal injuries may be linear or irregular. Perineal injuries may be superficial or deep. Perineal injuries may be painful or painless. Perineal injuries may be pruritic or nonpruritic. Perineal injuries may be erythematous or nonerythematous. Perineal injuries may be edematous or nonedematous. Perineal injuries may be vesicular or nonvesicular. Perineal injuries may be bullous or nonbullous. Perineal injuries may be pustular or nonpustular. Perineal injuries may be crusted or noncrusted. Perineal injuries may be scaly or nonscaly. Perineal injuries may be hyperpigmented or hypopigmented. Perineal injuries may be depigmented or repigmented. Perineal injuries may be scarred or unscarred. Perineal injuries may be atrophic or nonatrophic. Perineal injuries may be hypertrophic or nonhypertrophic. Perineal injuries may be keloidal or nonkeloidal. Perineal injuries may be calcified or noncalcified. Perineal injuries may be ossified or nonossified. Perineal injuries may be cartilaginous or noncartilaginous. Perineal injuries may be fibrous or nonfibrous. Perineal injuries may be adipose or nonadipose. Perineal injuries may be muscular or nonmuscular. Perineal injuries may be vascular or nonvascular. Perineal injuries may be neural or nonneural. Perineal injuries may be glandular or nonglandular. Perineal injuries may be mucosal or nonmucosal. Perineal injuries may be conjunctival or nonconjunctival. Perineal injuries may be oral or nonoral. Perineal injuries may be genital or nongenital. Perineal injuries may be anal or nonanal. Perineal injuries may be perianal or nonperianal. Perineal injuries may be perineal or nonperineal. Perineal injuries may be inguinal or noninguinal. Perineal injuries may be axillary or nonaxillary. Perineal injuries may be cervical or noncervical. Perineal injuries may be facial or nonfacial. Perineal injuries may be scalp or nonscalp. Perineal injuries may be hand or nonhand. Perineal injuries may be foot or nonfoot. Perineal injuries may be trunk or nontrunk. Perineal injuries may be extremity or n

CARCINOGENESIS

CHAPTER 109

+IRSQI -RVXEFNMRX (2%6I TEVW ERH' ERGIV

Kenneth H. Kraemer
Thomas M. Rünger

INTRODUCTION

The integrity of the genome of all living organisms is constantly threatened by exogenous and endogenous DNA-damaging agents. Exogenous DNA-damaging agents include physical agents, such as ultraviolet (UV) or ionizing radiation, and a wide variety of chemical agents, such as components of cigarette smoke. Endogenous DNA damage arises from regular metabolic processes within the cell, mediated, for example, by reactive oxygen species. Maintaining the stability of the genome is of utmost importance to all living organisms. Therefore, since early evolution, all organisms ranging from prokaryotes to eukaryotes have been equipped with mechanisms that react to and repair DNA damage and thereby maintain genomic stability. The types of damage produced include alterations in the structure of nucleotides, DNA strand breaks, DNA cross-links, and DNA adducts. Different types of DNA-damaging agents induce different types of DNA damage (Table 109-1), which in turn require different responses and repair pathways for processing (Table 109-2).[1]

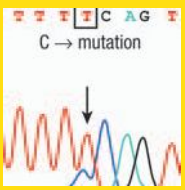
If DNA damage is not repaired adequately, it may lead to altered cell function, cell death, or the formation of mutations (alterations of the DNA sequence) in the damaged cells. These DNA damage–induced mutations will persist as long as the affected cell survives. At a cellular level, mutations in vital genes can lead to alterations of cell functions or malignant transformation. Accumulation of mutations may lead to organ dysfunction, aging, and cancer. Although most DNA damage is adequately repaired, none of the cellular responses is 100 percent effective in repairing all DNA damage under all circumstances.

A hereditary or acquired impairment in the way cells respond to DNA damage may result in genome instability with an increased rate of mutation formation. Numerous hereditary disorders are characterized by such genome instability (reviewed in Chap. 140). Many, but not all, of those are associated with an increased cancer risk and/or accelerated aging.

Exposure of the skin to UV light has multiple cellular and clinical effects, including an increase in skin cancer risk. The photocarcinogenesis cascade of events (Fig. 109-1) exemplifies the link between genome instability, DNA repair, and cancer. UV light produces a type of DNA damage involving the generation of photoproducts, which are alterations in the structure of nucleotides. The major DNA photoproducts are cyclobutane pyrimidine dimers (CPDs; Fig. 109-2) and 6,4-pyrimidine–pyrimidone dimers. Unrepaired CPDs or 6,4-pyrimidine–pyrimidone dimers may result in characteristic mutations: C to T single base and CC to TT tandem base substitution mutations.[2–4] Such mutations are typical for UV light exposures and only rarely are induced by other mutagens. They have therefore been termed 9 : WKH UHVXOW QYXEXSRW (see Fig. 109-2).

◀ Lentigo maligna melanoma. A large lentigo maligna on the left cheek with the typical variegation in color. The lesion is flat and macular and represents in situ melanoma. In the center of the irregular lesion there is a pitch-black nodule that indicates a switch from the radial to the vertical growth phase and thus invasiveness: The lesion is now called lentigo maligna melanoma.

GENOME INSTABILITY, DNA REPAIR, AND CANCER AT A GLANCE



- DNA can be damaged by physical agents (ultraviolet or ionizing radiation) or chemical agents in the environment.
- DNA damage may lead to mutations (changes in DNA sequence).
- The ability of cells to repair DNA damage and to maintain genome stability is of utmost importance to prevent malignant transformation.
- Different agents induce different types of DNA damage, which in turn require different responses and repair pathways.
- A number of hereditary disorders are characterized by genome instability due to defects in genes involved in DNA repair or DNA damage signaling.
- Many different laboratory tests can be used to diagnose genome instability and/or DNA repair defects.
- Inherited or acquired genome instability is associated with an increased cancer risk.

TABLE 109-1
Cellular Damage Induced by Physical and Chemical Agents

AGENT	DAMAGE
Ultraviolet radiation	Dipyrimidine cyclobutane dimers (TT, TC, CT, or CC), pyrimidine-pyrimidone (6-4) photoproducts (mostly TC), DNA-protein cross-links
X-irradiation	DNA single- and double-strand breaks, oxidative base damage (see below)
Psoralens plus ultraviolet A	DNA-psoralen monoadducts, DNA interstrand cross-links (binds to T at TA sequences)
Mitomycin C	DNA interstrand cross-links
Benzo-[a]-pyrene	Bulky adducts
Reactive oxygen species	Oxidative base damage (8-oxo-deoxyguanine, thymine glycol), cyclopurines (A or G) making bulky lesions

TABLE 109-2
Types of DNA Damage and Associated DNA Repair Pathways

TYPE OF DNA DAMAGE	DNA REPAIR PATHWAY
DNA photoproducts (CPDs, 6,4-PP)	Nucleotide excision repair
Oxidative base modifications (e.g., 8-oxoG)	Base excision repair
Incorrect DNA base pairing	Mismatch repair
DNA double-strand breaks	Non-homologous end joining, homologous recombination (i.e., recombination repair)
DNA adducts	Nucleotide excision repair
DNA cross-links (interstrand and intrastrand)	Recombination repair
Persistent DNA lesions	Translesion (bypass) DNA synthesis

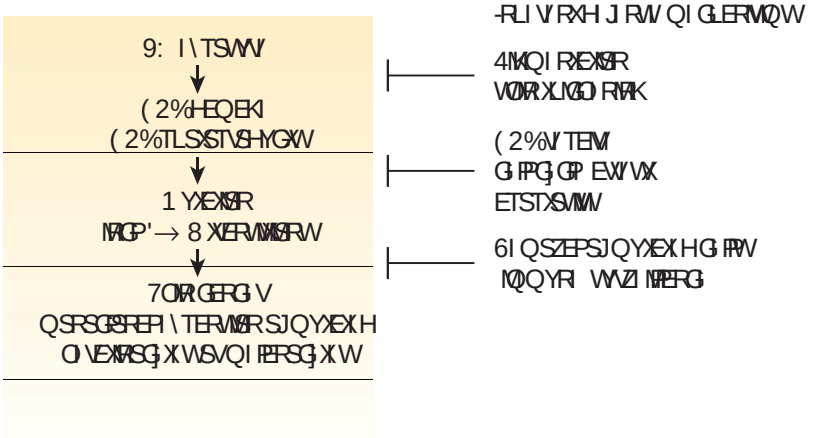
CPDs = cyclobutane pyrimidine dimers; 6,4-PP = 6,4-pyrimidine–pyrimidone photoproducts; 8-oxoG = 8-oxo-deoxyguanine.

DNA repair is an important cellular defense mechanism that prevents mutation formation at sites of DNA damage after UV exposure. However, it is not the only defense mechanism (see Fig. 109-1). Most mutations are generated during replication of damaged DNA. Therefore, a damage-induced arrest in cell cycling, which allows more time for repair, is another important cellular damage response that prevents mutation formation.[5,6] Furthermore, programmed cell death (apoptosis) prevents the survival of cells with overwhelming DNA damage, and through that mechanism the frequency of cells with UV-induced mutations is also reduced.[7] Other inherent defense mechanisms against the ultimately carcinogenic properties of UV light include increased melanogenesis and thickening of the epidermis and stratum corneum, which protect from future DNA damage, as well as removal of mutated cells through host immune responses (see Fig. 109-1).

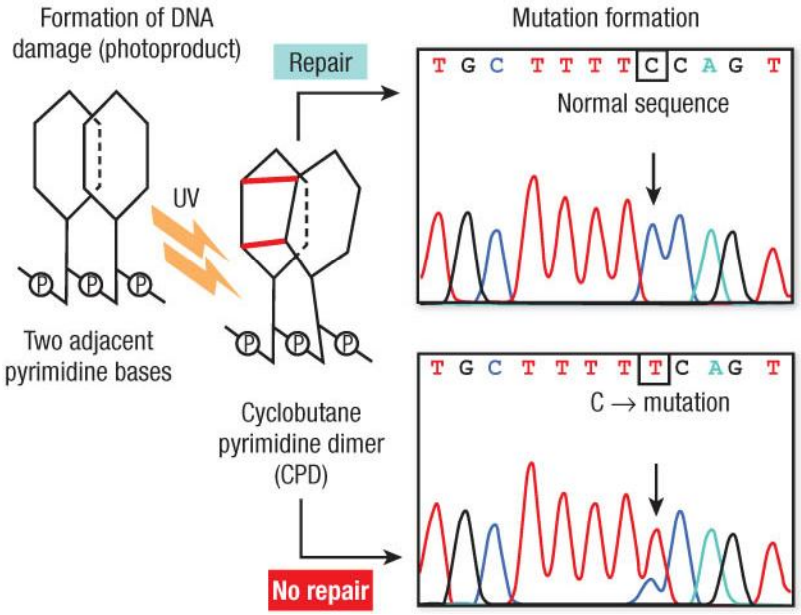
DNA DAMAGE AND REPAIR

More than 100 DNA repair genes have been identified (http://www.cgal.icnet.uk/DNA_Repair_Genes.html#NER). The nucleotide excision repair (NER) pathway acts on DNA damaged by UV radiation, repairing CPDs and other photoproducts, as well as on DNA damaged by certain carcinogens (such as benzo-[a]-pyrene) (see Table 109-2). In NER, the damaged nucleotide is removed and replaced with undamaged DNA. Multiple proteins act in concert to repair UV-induced DNA damage (Fig. 109-3). Defects in these repair genes can cause human diseases (Table 109-3), including xeroderma pigmentosum (XP), Cockayne syndrome, and trichothiodystrophy (for details on these disorders, see Chap. 140). For instance, XP can be caused by a defect in any one of several genes involved in NER. Based on cell fusion experiments, cells/patients with defects in the same gene are considered to be in the same complementation group, and in different complementation groups if different genes are affected. If DNA repair in the fused cell is normalized, with the wild-type gene from each cell giving rise to a functional protein that is absent in the other cell, the cells "complement" each other and are in different complementation groups. Seven such complementation groups have been identified (XPA to XPG), which implies that mutations in any of seven distinct genes can cause XP.

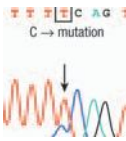
Transcribed genes are repaired faster than the rest of the genome. In the NER pathway, the first steps involving DNA damage recognition are different in non-transcribed and transcribed genes (global genome NER and transcription-coupled NER). In non-transcribed genes and noncoding areas, which represent most of the genome, the <4) and <4' gene products bind to UV-damaged DNA, marking it for further processing. In contrast, DNA damage in transcribed genes is probably sensed by a stalled

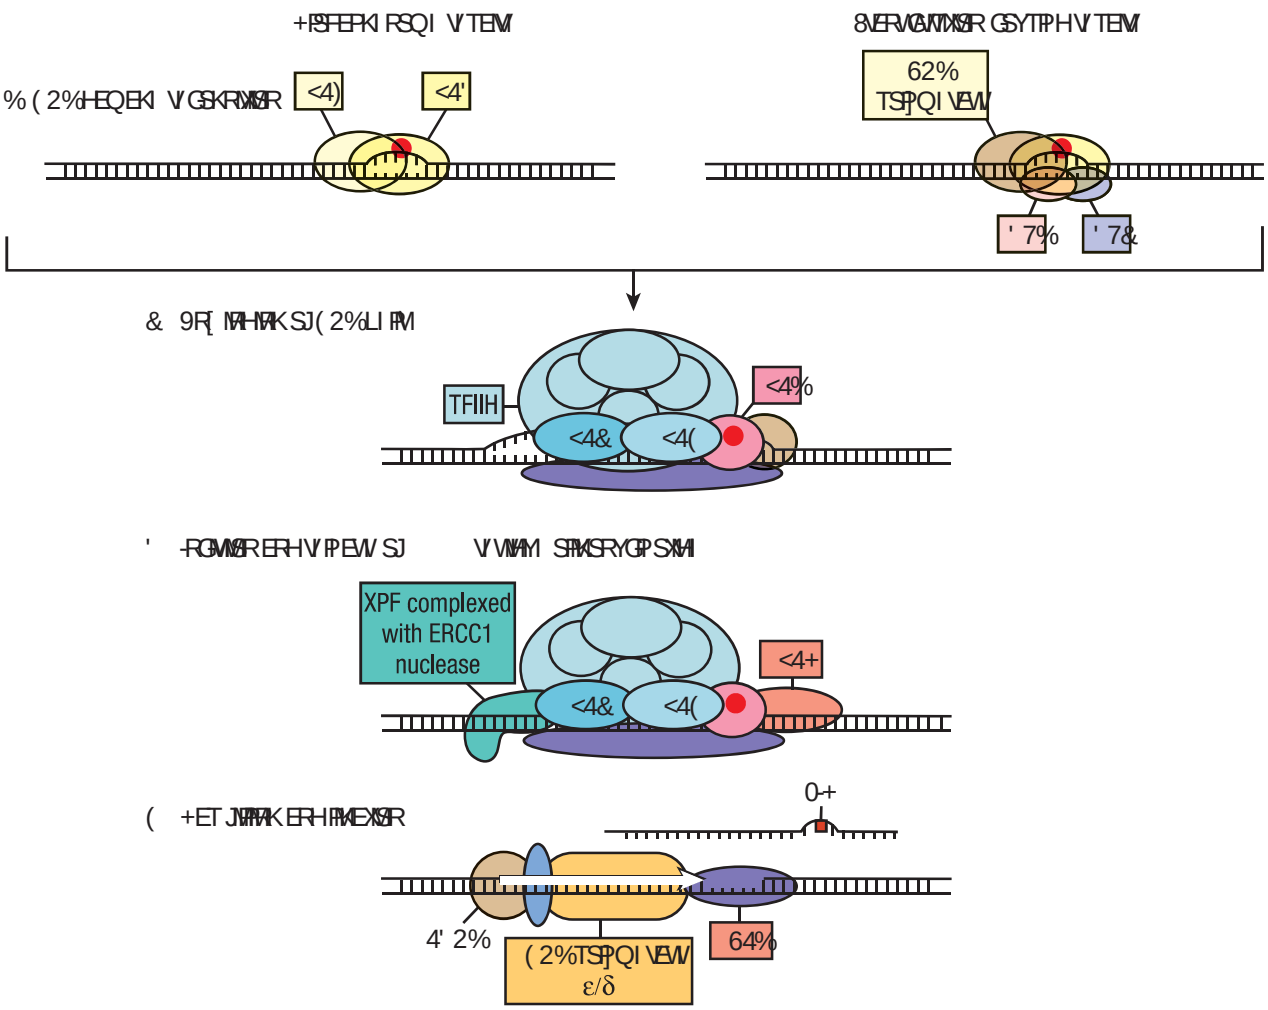


▲ *-+96) Photocarcinogenesis cascade of events. Exposure to ultraviolet (UV) light induces typical types of DNA damage, namely, cyclobutane pyrimidine and 6,4-pyrimidine–pyrimidone photoproducts. These often generate single and tandem base substitution mutations (C→T and CC→TT) that are typical for UV light exposure and are therefore termed *UV-signature mutations*. With sufficient numbers of inactivating mutations in crucial genes (tumor suppressor genes), individual cells may undergo malignant transformation, clonally expand, and form skin cancers. Several inherent defense mechanisms counteract this chain of events (see text).



◀ *-+96) Example of ultraviolet (UV) light–induced generation of DNA damage and a subsequent mutation. On direct excitation of the DNA molecule by UV light, adjacent pyrimidine bases (cytosine or thymine) may form covalent bonds between them, which leads to creation of pyrimidine dimers. The illustration shows an example in which two covalent bindings generate a tri-cyclic cyclobutane ring between two pyrimidines. Hence, this type of UV light–induced DNA damage is called a *cyclobutane pyrimidine dimer*, a common type of DNA photoproduct. The nucleotide excision repair DNA repair system functions to remove this damage, which results in the normal DNA sequence (*upper box*). If the damage is not repaired, this type of DNA photoproduct can lead to formation of a typical C⟶T single base substitution mutation (*lower box*). This is most likely to occur on replication of damaged DNA and misincorporation of adenine opposite the cytosine-containing photoproduct. An example of such a UV-signature mutation is shown on the right.[4] Note that the mutation is located within a run of seven pyrimidines, a common location for UV-signature mutations.



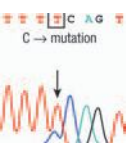


▲ *-+96) DNA nucleotide excision repair scheme. *%Right:* Damaged DNA in actively transcribed genes results in stalling of the RNA polymerase in a process that involves the CSA and CSB proteins. This serves as a signal to initiate transcription-coupled DNA repair. *Left:* Damaged DNA in the remainder of the genome is bound by the XPE and XPC gene products. This serves as a signal to initiate global genome repair. &A portion of the DNA, including the damage, is unwound by a complex of proteins including the XPB and XPD gene products. These proteins are also part of the 10-subunit basal transcription factor IIH (TFIIH). The XPA protein may stabilize the unwound DNA. ' The XPF and XPG nucleases make single-strand cuts on either side of the damage, releasing a 24- to 34-residue segment of DNA. (The resulting gap is filled by DNA polymerase in a process that includes the proteins proliferating cell nuclear antigen (PCNA) and replication protein A (RPA). CSA, CSB = Cockayne syndrome complementation groups A and B; ERCC1 = excision repair cross-complementing gene 1; LIG1 = ligase 1; XPA, XPC, etc. = xeroderma pigmentosum complementation groups A, C, etc.

TABLE 109-3
DNA Repair Genes Associated with Human Diseases

Gene[a]	Chromosome Location	Repair Pathway	Function
XPA	9q22.3	NER	Binding of damaged DNA
XPB (ERCC3)	2q21	NER	DNA helicase, part of TFIIH
XPC	3p25	NER	Binding of damaged DNA, global genome repair
XPD (ERCC2)	19q13.3	NER	DNA helicase, part of TFIIH
XPE (DDB2)	11p12-p11	NER	Binding of damaged DNA, global genome repair
XPF (ERCC4)	16p13.3-p13.11	NER	DNA endonuclease
XPG (ERCC5)	13q22	NER	DNA endonuclease
TTDA (GTF2H5)	6p25.3	NER	Part of TFIIH
CSA (ERCC8)	5q12	NER	Transcription-coupled repair
CSB (ERCC6)	10q11	NER	Transcription-coupled repair
XPV (polymerase eta)	6p21.1-p12	Bypass	DNA damage bypass polymerase
MSH2	2p22-p21	MMR	Mismatch repair (Muir-Torre syndrome, HNPCC)
MLH1	3p21.3	MMR	Mismatch repair (Muir-Torre syndrome, HNPCC)
PMS1	2q31-q33	MMR	Mismatch repair (HNPCC)
PMS2	7p22	MMR	Mismatch repair (HNPCC)
MSH6	2p16	MMR	Mismatch repair (HNPCC)
TFGBR	23p22	MMR	Mismatch repair (HNPCC)
MLH3	14q24.3	MMR	Mismatch repair (HNPCC)

ERCC = human excision repair cross-complementing genes that correct defects in cultured hamster cells; HNPCC = hereditary non-polyposis colon cancer; NER = nucleotide excision repair; MMR = mismatch repair; TFIIH = transcription factor IIH.
[a]The genes designated XP are defective in the corresponding xeroderma pigmentosum complementation group, and those designated CS are defective in the corresponding Cockayne syndrome complementation group.



RNA polymerase acting in conjunction with the CSA and CSB (Cockayne syndrome complementation groups A and B) gene products. After the DNA damage recognition steps, global genome NER and transcription-coupled NER follow the same pathway. The <4% gene product probably functions in conjunction with replication protein A, the transcription factor IIH (TFIIH), XPF, and excision repair cross-complementing gene 1 (ERCC1). The following steps occur in both non-transcribed and transcribed gene repair:

- The <4& and <4(gene products partially unwind the DNA in the region of the damage, thereby exposing the lesion for further processing. These proteins are part of the TFIIH basal transcription factor (see Fig. 109-3B).
- The <4* gene product, in a complex with ERCC1, makes a single-strand nick at the 5′ side of the lesion, whereas the <4+ gene product makes a similar nick on the 3′ side, which results in the release of a region of approximately 30 nucleotides containing the damage (see Fig. 109-3C).
- The resulting gap is filled by DNA polymerase using the other (undamaged) strand as a template in a process involving proliferating cell nuclear antigen. DNA ligase 1 seals the region, restoring the original undamaged sequence (see Fig. 109-3D).

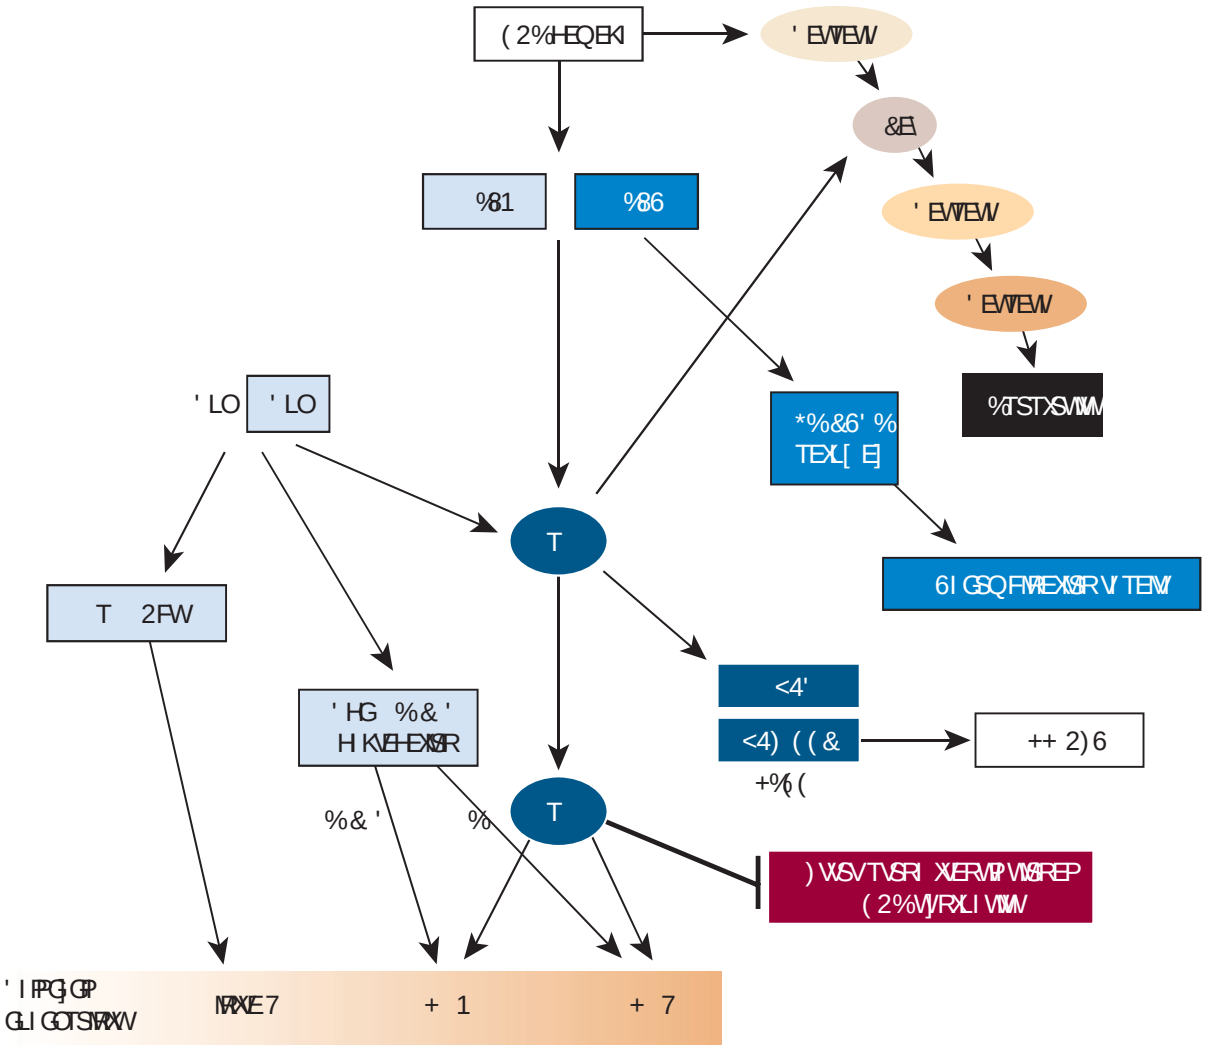
Other DNA repair pathways include base excision repair, recombination repair, and mismatch repair. Defects in mismatch repair are also associated with human diseases—Muir-Torre syndrome and human non-polyposis colon cancer. More extensive descriptions of these pathways may be found in refs. 1, 8, 9, and 10.

REGULATION OF CELLULAR RESPONSES TO DNA DAMAGE

As outlined in the introduction, several cellular responses to DNA damage contribute to the maintenance of genome integrity. These include cell cycle arrest, apoptosis (programmed cell death), and DNA repair.[5,11–18] Because these responses need to be carefully orchestrated, there are many proteins involved in the signaling of DNA damage and the regulation of DNA damage responses (Fig. 109-4). Different types of DNA-damaging agents and different types of DNA damage require different DNA damage responses. Fig. 109-4 presents some of the major players in signaling DNA damage and regulating DNA damage responses. As with defects in DNA repair genes (see Table 109-3), defects in many of these DNA damage–signaling genes (boxed in Fig. 109-4) are also implicated in hereditary disorders of genome instability (Table 109-4; for further details see Chap. 140).

The tumor suppressor gene p53, termed the KYEVHMER SJXLI KI RSQI,[19] plays a pivotal role in regulating and orchestrating these responses and is mutated in many cancers, including cutaneous squamous cell carcinomas. Upstream regulators of p53 in the cellular DNA damage response pathway are ATM (ataxia telangiectasia mutated) and ATR (ataxia telangiectasia- and Rad3-related) genes. One of p53's several functions is the regulation of the cell cycle in response to DNA damage. After cell division (mitosis), cells have 23 pairs of chromosomes and are in the G_1 phase of the cell cycle. The chromosomes then replicate during DNA synthesis, or S phase, and as a result have twice the number of chromosomes (G_2 phase) just before mitosis (M phase). The cell stops cycling (arrests) in specific cell cycle phases called GHPG GP GLIGOTSWPXWAn important downstream effector in preventing cells from entering S phase (G_1/S checkpoint) is p21.[5,11] p53 also induces NER by transcriptionally inducing XPC, XPE/p48, and GADD45.[20,21]

If cells enter S phase with unrepaired DNA damage, or if cells are UV exposed during S phase, regular DNA polymerases stall at DNA photoproducts and fall off the DNA strand. For these instances, cells are equipped with several specialized DNA polymerases for translesional DNA synthesis.[22] DNA polymerase eta is one of these; it is specialized to bypass DNA photoproducts but may introduce mutations while doing so.[23] It is mutated in XP variant, which is clinically indistinguishable from XP (see Table 109-3, Chap. 140).[24,25] This demonstrates the importance of this second line of defense against the mutagenic and carcinogenic consequences of DNA photoproducts. It was reported that p53 and



▲ *-+96) Signaling cascades that regulate apoptosis, DNA repair, translesional DNA synthesis, and activation of cell cycle checkpoints in response to DNA damage. This is a highly simplified diagram that depicts only the most important players in the intricate and interwoven DNA damage–signaling networks. The traditional thinking was that ATM (ataxia telangiectasia mutated gene) is activated (phosphorylated) in response to ionizing radiation (IR) and ATR (ataxia telangiectasia- and Rad3-related gene) is activated in response to ultraviolet (UV) radiation, but newer data indicate that both are activated by IR and UV. ATM/ATR can activate (i.e., phosphorylate) p53 either directly or indirectly through activation (phosphorylation) of Chk2 (an ATM target) or Chk1 (an ATR target). Through transcriptional activation of p21 and subsequent inhibition of cyclin-dependent kinases, which usually drive cells from the G_1 into the S phase of the cell cycle, activated p53 activates the G_1/S checkpoint (i.e., arrests cells in G_1). The G_1/S checkpoint is also activated by Chk1/Chk2-induced phosphorylation and then degradation of Cdc25A and subsequent failure to activate cyclin-dependent kinases. Phosphorylation and subsequent degradation of Cdc25A, Cdc25B, and Cdc25C also mediate the G_2/M arrest, as does p21. Intra–S phase arrest is mediated through activation (phosphorylation) of p95/Nbs1. p53 also induces global genome nucleotide excision repair (GG-NER) through transcriptional activation of XPC, XPE/p48, and GADD45. Translesional DNA synthesis has been shown to be downregulated by p53 via p21. Recombination repair is mediated through the Fanconi anemia (FA)/BRCA pathway, which in turn is dependent on ATR activation. The mitochondrial pathway of apoptosis is activated through activation of Bax by caspase 2 and p53, the initiator caspase 9, and the effector caspases 3, 6, and 7 (for references, see text). Gene products that are defective in hereditary human diseases are boxed. DDB2 = DNA damage binding protein 2; XPC, XPE = xeroderma pigmentosum complementation groups C and E.

p21 also downregulate the activity of this translesional DNA synthesis to maintain a low mutagenic activity at the price of reduced damage bypass.[26]

If this translesional DNA synthesis fails, cells can use recombination repair to resolve stalled replication forks.[27] When invoked in response to damage from UV light, this third line of defense is mediated by activation of the Fanconi anemia/BRCA DNA damage response pathway.[28] The exact mechanisms that initiate these DNA damage response signaling cascades is under investigation. Telomeres, which are repeats of TTAGGG that cap the ends of chromosomes and whose ends form a loop structure, are suggested to be important players in sensing DNA damage, for example, through opening of the telomere loop.[29] Other sensors may be stalled DNA or RNA polymerases, or proteins that detect bending of the DNA helix at sites of DNA damage.

Apoptosis is a regulated physiologic process leading to cell death characterized by cell shrinkage, membrane blebbing, and DNA fragmentation. A group of cysteine proteases called caspases are central regulators of apoptosis. Triggers may be extrinsic or intrinsic to the cell (e.g., DNA damage) and involve separate initiator caspases (e.g., caspase 2 in response to

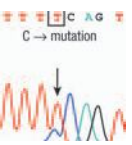


TABLE 109-4
DNA Damage–Signaling Genes Associated with Human Diseases

Gene	Chromosome Location	Hereditary Disorder
ATM	11q22.3	Ataxia telangiectasia

DNA damage) but share the same downstream effector caspases.[7]

APPROACHES TO DIAGNOSIS OF GENOME INSTABILITY AND/OR DNA REPAIR DEFECTS

When a disorder of genome instability is suspected, the clinician is challenged with choosing the appropriate laboratory tests to secure a diagnosis and to provide guidance for affected patients and families. Table 109-5 lists some hallmark clinical features that may indicate the presence of such disorders and should prompt clinicians to initiate testing. Various laboratory tests for genome stability, DNA repair, and response to physical and chemical agents are listed in Table 109-6.

Use of Cultured Cells

Cells obtained directly from patients and grown in culture medium are termed TWM QEY GPXVW Dermal fibroblasts generally grow easily in culture and can generally be established from a 2- to 4-mm sterile skin punch biopsy specimen. The inner surface of the upper arm has proven to be a suitable biopsy site because this area heals easily, the resulting scar is not readily visible, the site is shielded from UV radiation, and attempts to establish cultures from specimens are generally successful. The tissue is placed in sterile culture medium (or sterile saline) with antibiotics and transported to a cell culture laboratory at room temperature.

Human cell cultures are made available for research by the National Institutes of Health–funded Human Genetic Mutant Cell Repository (401 Haddon Ave, Camden, NJ 08103; telephone: 856-966-7377; http://ccr.coriell.org/Sections/Collections/NIGMS/SsId=8).

Diagnostic Tests of Genome Instability and DNA Repair

Tests to assess genome instability and/or DNA repair capacity may be divided into tests of intact cellular function and tests of chromosome integrity and breakage in response to DNA-damaging agents. Other tests measure the mechanism of impairment of a cell function such as DNA repair or characterize or determine the expression of defective genes (see Table 109-6).

8) 787 3* -28% 8 ') 00 *92' 8-32 Tests of cellular function measure the capacity of the intact cell to recover from DNA damage. These tests do not provide information regarding the specific type of damage resulting in cellular injury or the mechanism of cellular recovery, but they do form

TABLE 109-5
Hallmark Clinical Features That May Indicate a Disorder of Genome Instability or DNA Repair and Prompt Clinicians to Initiate Testing[a]

Disorder	Clinical Features
Xeroderma pigmentosum	Congenital photosensitivity, childhood freckling, early or multiple skin cancers
Cockayne syndrome	Congenital photosensitivity, postnatal growth failure, sensorineuronal deafness
Trichothiodystrophy	Brittle hair, photosensitivity, ichthyosis
Ataxia telangiectasia	Telangiectasias, ataxia, leukemias, and lymphomas
Bloom syndrome	Photosensitivity, malar erythema, growth retardation
Fanconi anemia	Aplastic anemia, growth retardation, café-au-lait spots, thumb abnormalities
Muir-Torre syndrome	Sebaceous tumors, keratoacanthomas, personal or family history of colon cancer

TABLE 109-6
Diagnostic Tests of Genome Stability, DNA Repair, and Response to Physical or Chemical Agents[a]

- Intact cell function (proliferation or cell death)
  - Cell counts (growth in mass culture)
  - Thymidine incorporation
  - Colony-forming ability
- Chromosome integrity and breakage
  - Giemsa-stained metaphase karyotype analysis
  - G_2 chromosome breakage
  - Sister chromatid exchanges
  - Fluorescent in situ hybridization
  - Microsatellite instability testing
- DNA repair
  - Unscheduled DNA synthesis
  - RNA synthesis inhibition
  - Host cell reactivation
  - Comet assay
  - Immunological analysis of DNA damage and removal (enzyme-linked immunosorbent assay, slot blot)
  - Microsatellite instability testing
- Characterization and expression of defective genes
  - Real-time polymerase chain reaction
  - Western blotting
  - DNA sequencing

[a]Agents are listed in Table 109-1.

TABLE 109-7
Suggested Sequence of Diagnostic Testing for Diseases of Genome Instability or DNA Repair[a]

Disease	Step 1	Step 2	Step 3	Step 4	Testing Available[b]
Xeroderma pigmentosum	Post-UV hypersensitivity	Post-UV DNA repair	DNA sequencing	—	CLIA/R
Xeroderma pigmentosum variant	Post-UV hypersensitivity (with caffeine)	Post-UV DNA repair (normal)	DNA sequencing	—	R
Cockayne syndrome	Post-UV hypersensitivity	Post-UV inhibition of RNA synthesis	DNA sequencing	—	CLIA
Trichothiodystrophy[c]	Post-UV hypersensitivity	Post-UV DNA repair	DNA sequencing	—	CLIA/R
Ataxia telangiectasia	Chromosome breakage	X-ray hypersensitivity	Western blotting for level of protein	DNA sequencing	CLIA/R
Bloom syndrome	Chromosome breakage	Sister chromatid exchange	DNA sequencing	—	CLIA
Fanconi anemia	Chromosome breakage	Hypersensitivity to DNA cross-linking agents	Western blotting for FANCD2	DNA sequencing	CLIA/R
Muir-Torre syndrome	Microsatellite instability	Western blotting for level of protein	DNA sequencing	—	CLIA

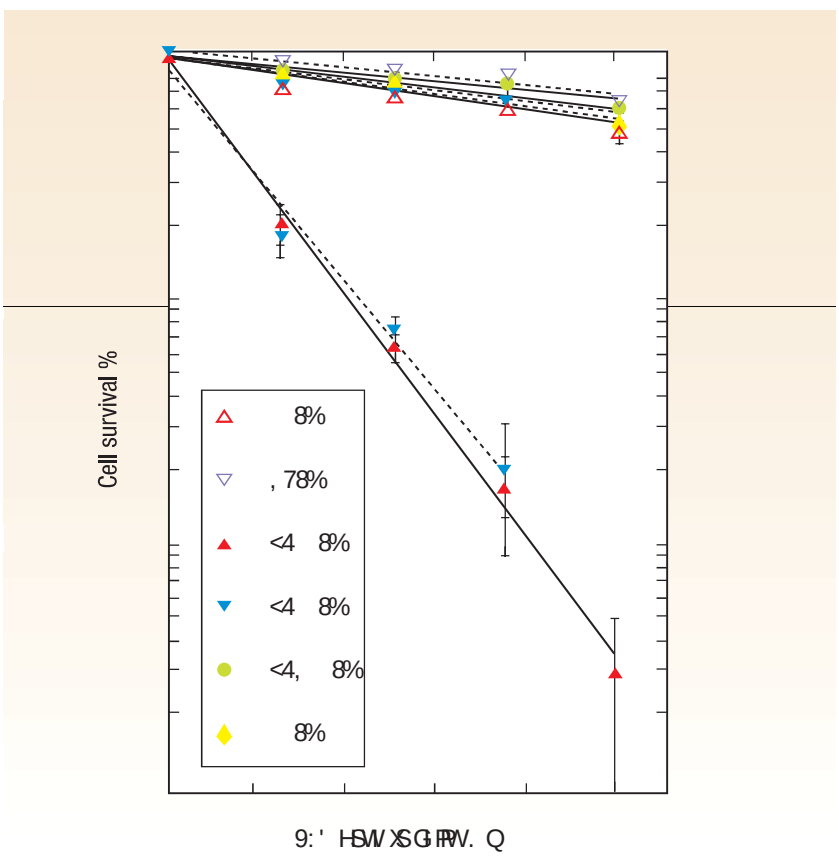
CLIA = testing available by laboratories certified under the Clinical Laboratory Improvement Act; R = research testing available; UV = ultraviolet radiation.
[a]These are suggestions only and may change based on availability of different assays or new scientific information.
[b]Testing laboratories are listed on the National Institutes of Health–funded website http://genetests.org.
[c]Screen by polarizing microscopic examination of hair followed by measurement of sulfur-containing amino acids in the hair (see Chap. 140).

the basis for identifying cells as hypersensitive to DNA-damaging agents and are often used as simple screening tests.

Cell Counts or Thymidine Incorporation. One of simplest tests after exposure to UV radiation or x-rays is the assessment of the growth rate in mass culture by using a microscope or an automated cell counter to count the number of cells or by measuring incorporation of radioactive thymidine into newly synthesized DNA (see Tables 109-6 and 109-7).

Colony-Forming Ability. A test of colony-forming ability assesses the capacity of a single cell to proliferate enough to form a visible colony (Fig. 109-5).

8) 787 3* ', 631 3731) -28) +6-8= %2(&6) % %+) ***Chromosome Breakage.*** Chromosome breakage is usually assessed in primary cultures of mitogen-stimulated peripheral blood leukocytes or in long-



9: ' HSW/ XSG HPV. Q

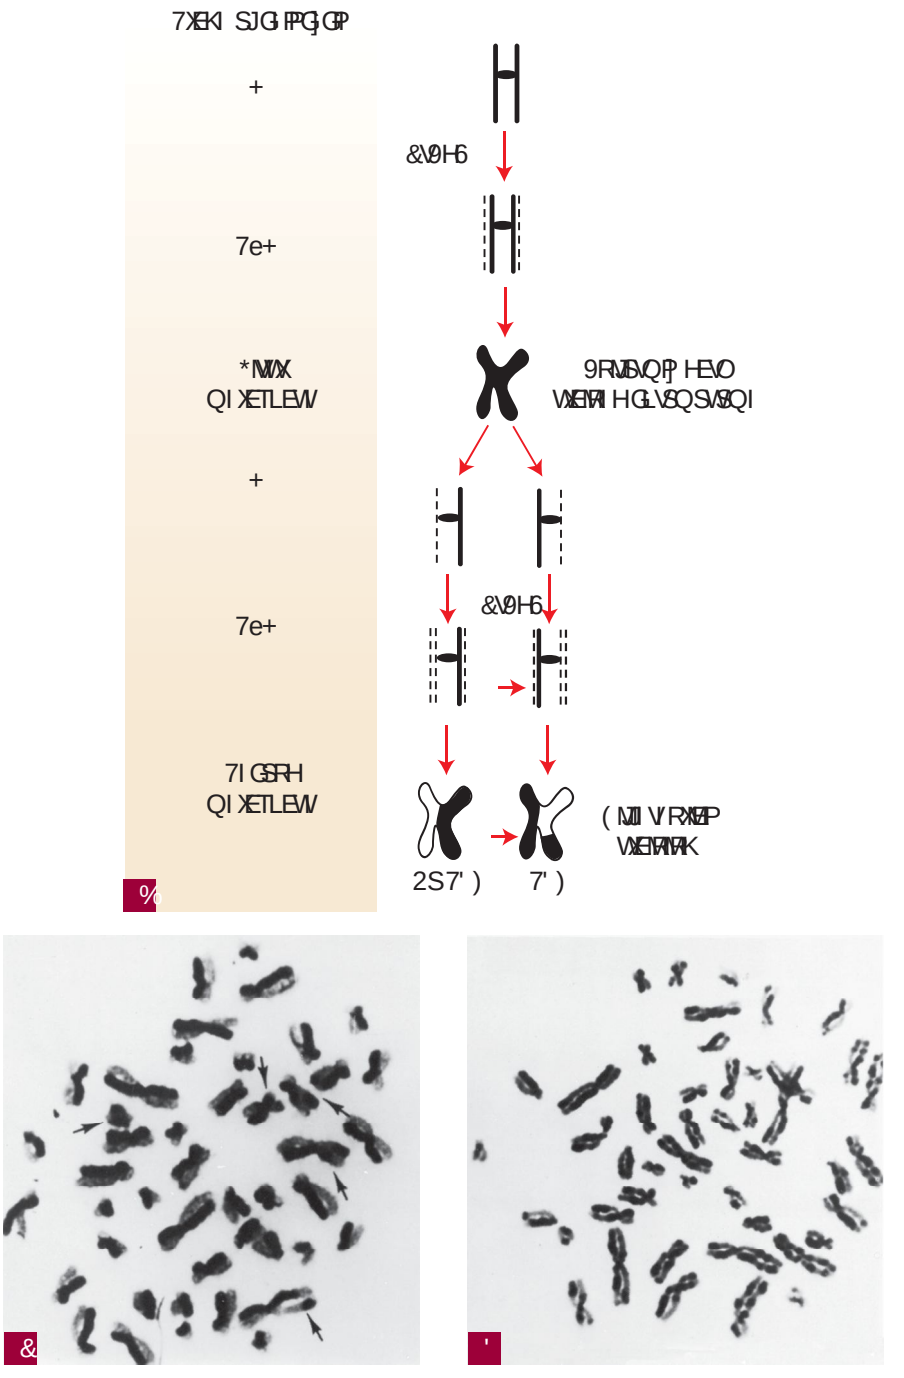
◀ *-+96) Colony-forming ability assay of cell sensitivity. Xeroderma pigmentosum (XP) fibroblasts from two affected siblings (XP12TA and XP25TA), their father (XPH27TA), and an unaffected brother (35TA) as well as normal fibroblasts (96TA and HSTA) were treated with 254-nm ultraviolet C (UVC) radiation and colony-forming ability was determined. The XPC (XP complementation group C) fibroblast strains from the affected siblings were much more sensitive than the normal strains and showed similar post-UVC hypersensitivity. Cells from the unaffected brother and the clinically normal father, a heterozygous carrier of the XPC defect, had normal post-UVC survival. (Modified from Slor H et al: Clinical, cellular, and molecular features of an Israeli xeroderma pigmentosum family with a frameshift mutation in the XPC Gene: Sun protection prolongs life. *J Invest Dermatol* :974, 2000.)

term cultures of fibroblasts or lymphoblastoid cell lines. Cell cycle progression is stopped at metaphase by treatment of the cells with an inhibitor of mitosis such as colchicine. In this procedure, the 23 pairs of metaphase chromosomes from a single cell are spread over a discrete area of the slide and stained (usually with Giemsa stain). Preparations may be analyzed for the number of chromosomes per metaphase, the morphology of the individual chromosomes, and the attachments or rearrangements of chromosomes in relation to each other.

Sister Chromatid Exchange. During DNA replication, chromatids occasionally exchange positions along the arms of a chromosome. This sister chromatid exchange may be detected by permitting the cells to grow through two cycles of replication in medium containing the nucleic acid analog bromodeoxyuridine (Fig.109-6). Sister chromatid exchanges are thought to be related to DNA recombination repair, although their precise significance is not understood.

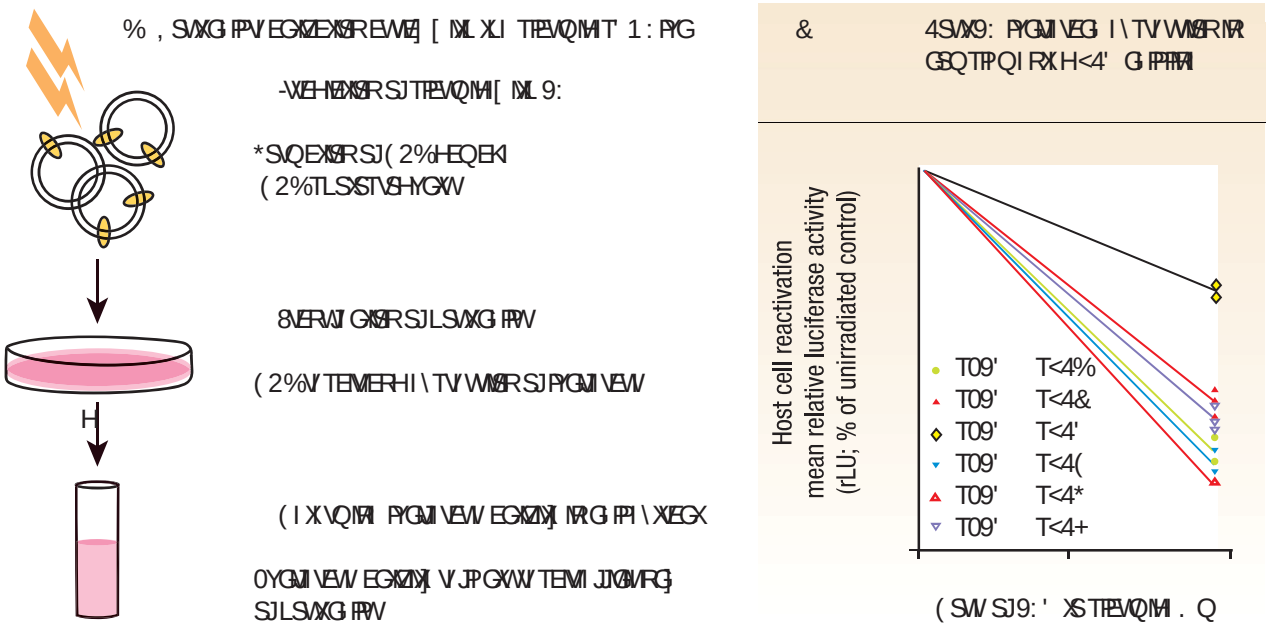
8) 787 3* (2%6) 4%6 ***Unscheduled DNA Synthesis.*** One of the most commonly used tests of NER is unscheduled DNA synthesis. This test has been used to measure DNA repair in intact human skin, in cultured epidermal or dermal cells, and in blood cells, and for prenatal diagnosis using amniotic fluid cells. Unscheduled DNA synthesis testing measures the repair-associated DNA synthesis in G_1 or G_2 cells (which usually do not synthesize DNA). Cells are treated with UV radiation or another DNA-damaging agent and then incubated in medium containing radioactive thymidine. During the process of NER, the damage is removed and the radioactive thymidine is incorporated into the repaired region. The cells are treated with fixative, coated with autoradiographic (photographic) emulsion, and kept in the dark for an appropriate interval, and then the emulsion is developed. UV radiation of normal fibroblasts results in a large increase in the number of grains seen over all the nuclei. In marked contrast, irradiation of the XP fibroblasts that cannot repair DNA damage results in very few grains over the nuclei.

RNA Synthesis Inhibition. After exposure to UV radiation, normal cells temporarily reduce RNA synthesis from active genes. Synthesis resumes when the damage is repaired. This resumption of RNA synthesis is delayed in cells from patients with Cockayne syndrome and some forms of XP.



▲ *-+96) %Sister chromatid exchange (SCE) assay of chromosome integrity. After the first cycle of replication, the DNA of the newly synthesized strand is labeled with bromodeoxyuridine (BrUdR), whereas the older strand is unlabeled. Such chromosomes appear uniformly dark with Giemsa stain. After a second cycle of replication in BrUdR-containing medium, one arm of a chromosome will contain two labeled chromatids, whereas the other will contain one labeled and one unlabeled chromatid. The doubly substituted arm will stain lightly, whereas the singly substituted arm will stain darkly. If an SCE occurred during replication, a portion of each chromosome arm will be doubly substituted and the remainder singly substituted with BrUdR. & Undamaged normal cultured peripheral blood lymphocytes have approximately 10 SCEs per metaphase. ' Cultured peripheral blood lymphocytes from a patient with Bloom syndrome have a manifold increase in SCEs. (From Chaganti RS, Schonberg S, German J: A manyfold increase in sister chromatid exchanges in Bloom's syndrome lymphocytes. *Proc Natl Acad Sci U S A* :4508, 1974, with permission.)

Host Cell Reactivation. The host cell reactivation assay relies on the fact that plasmids do not have the ability to repair



▲ *-+96) Plasmid host cell reactivation assay with assignment to xeroderma pigmentosum (XP) complementation group. %The plasmid is damaged by ultraviolet (UV) radiation and introduced into cultured human cells by a transfection technique. The cells' DNA repair enzymes repair the damage in a manner similar to the repair of cellular DNA. Repaired DNA will then function to transcribe the plasmid-encoded luciferase gene in the human cell. The amount of luciferase activity within the host cells therefore reflects the efficiency of the cellular DNA repair system. This assay can also be used to determine the complementation group by co-transfecting UV-treated plasmid plus plasmids expressing wild-type XP complementary DNA (cDNA). &The results of plasmid host cell reactivation experiments and complementation group assignment with DNA excision repair–deficient XP46DC cells. UV-treated plasmid showed low expression in the XP65BE cells that was increased only by co-transfection with a plasmid expressing the wild-type XPC cDNA. This result indicates that XP65BE cells are in XP complementation group C (XPC). rLU = relative light units; pCMVluc and pLUC = plasmids containing gene for luciferase; pXPA–pXPG = plasmids expressing xeroderma pigmentosum complementation groups A–G.

damage to their DNA but depend on cellular repair systems. Thus, damaged plasmids would be expected to be expressed at a higher level in cells with normal repair capacity. A non-replicating plasmid that contains the gene for the firefly enzyme luciferase, constructed to permit expression in human cells,[30] is widely used; generation of light provides a quantitative endpoint for its repair (Fig. 109-7).

Comet Assay. The comet assay is a single cell–based technique that allows detection and quantitation of DNA damage. Damaged nuclei are embedded in agarose, lysed, and exposed to an electric field. The DNA migrates out of the nucleus forming a "comet" when stained. The length of the comet is proportional to the fragmentation of the DNA. This assay can be modified for detection of single-strand or double-strand DNA breaks, UV damage, or oxidative DNA damage. Cells from patients with XP have defective repair in the post-UV comet assay.

Microsatellite Instability. Normal DNA has tens of thousands of regions with repeats of the dinucleotide CA or other short motifs up to five nucleotides long. In normal individuals each of these microsatellites (also called VWQTPP VWUYIRG VTTIEXWr VWSXXERHQ VTTIEXW has a uniform size. However, these sizes are highly variable among different individuals and are often used for DNA "fingerprinting." The appearance of abnormally longer or shorter simple sequence repeats in different tissues or tumors from a patient is called QMGSVEXFPPX MR VXEFMRX. This can be associated with a defect in mismatch repair genes.

', %6% 8) 6->%8-32 %2( ) <46) 77-32 3* ( )*)' 8-:) +) 2) 7 ***Real-Time Polymerase Chain Reaction.*** In some genome instability genes, mutations create premature stop codons for protein synthesis. These mutations result in low levels of messenger RNA (mRNA) for the gene product through a process called RSRWMRW QIHMPXHQIWMPK HIGE. The mRNA levels can be accurately measured by use of quantitative reverse transcriptase real-time polymerase chain reaction. For example, low XPC mRNA levels have been found in cells from most XP patients with defects in this gene.[31]

Western Blotting. Some mutations result in reduced levels or size of encoded proteins, often through creation of premature stop codons.[31] Reduced protein levels are most commonly detected by Western blotting. Cells are lysed and the proteins are extracted and separated by gel electrophoresis. The separated proteins are transferred to a membrane and probed with an antibody that is specific for the protein of interest. The intensity of the antibody staining reflects the amount of protein in the cells, and its location on the membrane is an indication of the size of the protein molecules.

DNA Sequencing. Direct sequencing of defective genes is the gold standard for determination of the presence of a mutation. The final step in confirmation of a diagnosis may be DNA sequencing to determine the disease-causing mutation. By definition, disease-causing mutations alter the function of genes. Of note, however, not every alteration in the sequence of a gene alters the function of the encoded protein. In the human genome there are millions of single nucleotide polymorphisms, or changes in one nucleotide, that are not associated with disease and may not even change the amino acid composition of

the encoded protein. In recessive disorders, each clinically unaffected parent has one normal allele and one potentially disease-causing mutation in the other allele. The affected child receives an allele with a disease-causing mutation from each parent. The two mutations must be in the same gene, although they need not necessarily be identical to each other.

Considerations in Diagnostic Testing

Diagnosis of disorders of genome instability or DNA repair is often a multistep process. A suggested sequence of steps is listed in Table 109-7. As new tests are developed and new information is obtained about these disorders, testing procedures may change accordingly. In addition, decisions regarding the extent of testing performed may be made with consideration of how much the tests cost and whether additional information would alter treatment. For example, DNA sequencing is rarely required for establishment of a diagnosis of XP in a child with classical clinical features and cells that are hypersensitive to killing by UV and have defective DNA repair. But if a family has one child affected with XP and is considering having additional children, DNA sequencing might offer them the possibility of prenatal diagnosis through DNA sequencing of a trophoblast biopsy specimen.

Genetic counseling is an important component of patient management for these genetic diseases. This function may be performed by the treating physician or by a trained genetic counselor.

In the United States, only laboratories certified in accordance with the Clinical Laboratory Improvement Act (CLIA) are allowed to perform these specialized tests in the context of patient care. Tests performed in research laboratories generally have limited use in clinical practice. However, a research laboratory may identify a disease mutation in cells from a patient that could then be confirmed in a CLIA-certified laboratory and used in clinical practice. A listing of laboratory testing facilities for these diseases may be found at the website http://genetests.org, funded by the National Institutes of Health.

CUTANEOUS CANCER AND PUBLIC HEALTH

Cutaneous cancers account for more than one-half of all malignancies diagnosed in the United States, totaling more than 1 million non-melanoma skin cancers (NMSCs) [800,000 to 900,000 basal cell carcinomas (BCCs) and 200,000 to 300,000 squamous cell carcinomas (SCCs)] and over 62,000 melanomas, according to estimates for 2006 by the American Cancer Society. The precise number of NMSCs is unknown, because unlike other malignancies, they are not routinely reported to registries. Although only a small fraction of patients with NMSC will die from their disease, which is nearly always SCC, the frequency of these cancers nonetheless results in an estimated death rate between 1000 and 2000 per year. In contrast, although much less common than NMSC, melanoma has a death rate estimated at nearly 8000 per year,[1] and a staggering 1 in 59 individuals born today is predicted to develop melanoma during his or her lifetime, based on 2001–2003 data compiled by the National Cancer Institute's Surveillance Epidemiology and End Results program (http://www.seer.cancer.gov). Because they are so common, cutaneous cancers have a major impact on health care costs: in addition to the mortality burden, treatment is associated with considerable morbidity and cosmetic defects. For these reasons, understanding the etiology and pathogenesis of these malignancies is a significant public health goal, and development of rational, non-deforming therapies to reduce morbidity and mortality is urgently needed. The high prevalence of skin cancer, the external location of the tumors, and well-defined pre-neoplastic lesions all provide an excellent opportunity for studying the factors regulating cutaneous cancer induction in humans. Those qualities that facilitate the study of cutaneous neoplasms in human populations have also been useful in establishing relevant animal models. Advances in molecular genetics, keratinocyte cell culture, and development of genetically altered mice and reconstructed human skin models have greatly facilitated the analysis of basic mechanisms of cutaneous carcinogenesis. The main focus of this chapter is on NMSC: the reader is referred to Chap. 124 for further discussion of melanoma.

CHEMICALS ASSOCIATED WITH SKIN CANCER INDUCTION IN HUMANS

The ultraviolet radiation (UVR) in sunlight is the primary etiologic agent for all skin cancers, and, thus, UVR is the major carcinogen in the human environment. The powerful carcinogenic activity of UVR is attributable to its ability to damage DNA and cause mutations, its capacity to clonally expand incipient neoplastic cells whose altered signaling pathways provide a survival advantage in the face of ultraviolet-induced cytotoxicity, its ability to induce reactive oxygen species, and its activity as an immune suppressant (see Chap. 112). The association of UVR with skin cancer is so strongly supported by clinical, epidemio-

CHEMICAL CARCINOGENESIS AT A GLANCE

- More than 200 chemicals have been linked to human cancer development.
- Chemicals implicated in human skin cancer development include polycyclic aromatic hydrocarbons and arsenic.
- Chemical carcinogenesis studies in mouse skin have defined operational stages of epithelial carcinogenesis, which include initiation, promotion, and malignant progression. Based on their activity in this assay, chemicals linked to human cancer can be classified as tumor initiators, promoters, or "complete" carcinogens.
- Tumor initiation is irreversible, because it is associated with gene mutations that permanently alter the biologic responsiveness of the initiated cell; tumor promotion is a non-mutagenic process that provides a selective growth advantage to initiated cells and is reversible at early stages; agents that facilitate malignant progression are generally genotoxic.
- Most carcinogens must undergo metabolic activation that involves several enzymes involved in xenobiotic metabolism, including cytochrome p450 enzymes and glutathione S-transferase.
- An individual's likelihood of developing chemically induced skin cancer is a function of exposure history, presence of additional risk factors, and genetic background, including gene polymorphisms that influence susceptibility to chemical carcinogens.

logic, and experimental data that it represents the most clear-cut etiologic factor in human malignancy. Also implicated in the development of human skin cancer are various chemicals as a result of environmental, occupational, or medicinal exposures (Table 110-1). In 1775, Sir Percivall Pott[2] attributed the increased incidence of scrotal cancer in chimney sweeps to repeated exposure to soot. This report provided the first link between occupational exposure and the development of cancer as well as the first example of chemical carcinogenesis. According to the National Toxicology Program's 11th Report on Carcinogens, published in 2005, (http://ntp.niehs.nih.gov/ntp/roc/toc11.html), 246 agents are listed as known or likely human carcinogens, and the great majority of these are chemicals. In the last 35 years, the mechanisms by which chemicals cause cancer have been unraveled and reveal striking similarities to the properties responsible for UVR carcinogenicity, namely DNA damage, selective cytotoxicity, and immune suppression. The carcinogenic potential of coal and petroleum derivatives is now firmly established as a result of experimental animal studies and epidemiologic reports. Petroleum products and grease, as well as insecticides, herbicides, and fungicides, are particularly pathogenic for SCC, while fiberglass and dry-cleaning agents increase the incidence of BCC.[3] Cigarette and pipe smokers have an overall twofold increased risk for cutaneous SCC, and the risk increases with the intensity of the tobacco use.[4]

Arsenic exposure is associated with the development of pre-malignant keratoses, Bowen disease, SCC, and BCC, as well as a number of internal malignancies.[5] Although Fowler's solution (1 percent potassium arsenite) is no longer used in medical practice, certain herbal medicines are still a source of arsenic exposure. Occupational exposures to arsenic as a component of agricultural pesticides, sheep and cattle dip, mining and smelting, glass manufacturing, and other industries are well documented. A more insidious source of environmental arsenic exposure is contaminated drinking water or shellfish, and analysis of affected populations shows a dose-dependent increase in skin cancer.[6] Mouse models have provided evidence for an interaction of ingested arsenic acting as a co-carcinogen with solar radiation to increase the frequency and size of cutaneous carcinomas and reduce the latency period.[7,8]

A variety of medications have been associated with the development of skin cancer. Systemic treatment with immunosuppressive agents results in an increased incidence of both benign and malignant skin lesions,[9] which is generally attributed to reduced immune surveillance of nascent tumor cells. However, a more specific mechanism predisposing to skin cancer has been proposed for azathioprine, which may sensitize DNA to ultraviolet A radiation via its metabolite, 6-thioguanine, leading to the production of mutagenic reactive oxygen species.[10] Topical nitrogen mustard also increases the risk of developing skin cancer. Despite the clear-cut association between occupational exposure to tars and skin cancer, the use of crude coal tar in the treatment of psoriasis appears to pose a relatively low risk for the development of skin tumors. In contrast, the use of ionizing radiation to treat a variety of skin diseases increases the risk of BCC in all treated patients and SCC in individuals with sun-sensitive skin.[11]

Systemic administration of psoralen and ultraviolet A light (PUVA) is associ-

TABLE 110-1
Environmental Agents Associated with the Development of Human Skin Cancer

Agent	Individual at Risk	Route of Exposure	Tumor Types
Ultraviolet radiation	General population	T	BCC, BD, SCC, M
Cigarette smoke	Smokers	T or S	SCC
Soot	Chimney sweep	T	SCC
Coal tar, pitch	Coker of coal, steelworker	T	SCC
Petroleum oils	Machinist, textile worker	T and S	SCC
Arsenic	Agriculture worker, etc.	S and/or T	BD, SCC, BCC
4,4′-Bipridyl	Pesticide manufacturer	T	SCC, BD
Polychlorinated biphenyl	Petrochemical worker	T or S	M
Dry-cleaning reagents	Dry cleaners	T or S	BCC
Fiberglass	Insulators	T	BCC
Psoralen (PUVA)	Psoriasis patient	T and S	SCC, BCC, M
Nitrogen mustard	Cutaneous T-cell lymphoma patient	T	SCC
Immunosuppressants	Transplant recipients, etc.	S	SCC, BCC
Ionizing radiation	Various skin disorders	T	BCC, SCC

BD = Bowen disease; BCC = basal cell carcinoma; M = melanoma; PUVA = psoralen and ultraviolet A; S = systemic; SCC = squamous cell carcinoma; T = topical.

ated with a dose-dependent increase in the risk of developing cutaneous SCC that persists after discontinuation of therapy.[12]

THE NATURE OF CHEMICAL CARCINOGENS: CHEMISTRY AND METABOLISM

How can such a diverse group of chemical and physical agents contribute to cutaneous cancer when the great majority of environmental agents to which humans are exposed are not carcinogenic? We now know that carcinogens can be genotoxic, non-genotoxic, or both.[16] Genotoxic carcinogens have high chemical reactivity (such as alkylating agents like nitrogen mustard) or can be metabolized to reactive intermediates by the host (such as petroleum products). They form covalent adducts with macromolecules and target DNA in the nucleus and mitochondria.[17] Because there is a good correlation between the ability to form covalent DNA adducts and the potency to induce tumors in laboratory animals, DNA is considered the ultimate target for most genotoxic carcinogens. The interaction with DNA is not random, and each class of agents reacts selectively with purine and pyrimidine targets.[17] Furthermore, targeting of carcinogens to particular sites in DNA is determined by nucleotide sequence, by host cell, and by selective DNA repair processes making some genetic material at risk over others. As expected from this chemistry, genotoxic carcinogens are potent mutagens, particularly adept at causing base mispairing or small deletions, leading to missense or nonsense mutations. Others may cause macrogenetic damage such as chromosome breaks and large deletions. In all cases, mutations detected in tumors represent a combination of the effect of the mutagenic change on the function of the protein product and the effect of the functional alteration on the behavior of the specific host cell type.

A number of chemicals that cause cancers in laboratory rodents and contribute to human skin cancer incidence are not demonstrably genotoxic.[18] Synthetic pesticides and herbicides, dry-cleaning reagents, and arsenic may fall within this group. The mechanism of action by non-genotoxic carcinogens is controversial and may be related in some cases to toxic cell death and regenerative hyperplasia. Induction of endogenous mutagenic mechanisms such as DNA oxyradical damage,[19] depurination of DNA, and deamination of 5-methylcytosine may contribute to carcinogenicity of these agents. Non-genotoxic carcinogens may interfere with host protective mechanisms as has been suggested for the action of arsenic in suppressing DNA repair or inhibiting the activity of tumor suppressor genes.[7] Thus, non-genotoxic carcinogens may serve as modifiers in concert with genotoxic agents such as UVR.

A number of metabolic pathways activate or detoxify carcinogens and procarcinogens (chemicals that can be transformed into active carcinogens).[20] These pathways are complex and interactive,[21] and genetic polymorphisms both in animal models and humans contribute to cancer susceptibility.[22] In general, metabolic activation of carcinogens involves oxidation at carbon–carbon double bonds or saturated carbon atoms, or oxidation or reduction at nitrogen moieties, yielding reactive intermediates that bind to DNA. Conjugations are also frequent intermediates of metabolism of many carcinogens and can be both activating and detoxifying pathways.[21] Metabolic activation of carcinogens and the polymorphic nature of metabolic activity among individuals provide an approach to estimate individual risk profiles for particular exposures. Furthermore, a number of metabolic pathways are inducible and modified by diet, hormones, and additional exposures, adding further complexity to the process of carcinogenesis.

HEREDITARY CANCER SYNDROMES

If DNA is the target for carcinogens, and mutagenesis is the underlying mechanism of cancer pathogenesis, how do we determine the genetic targets that contribute to the phenotype of cutaneous neoplasms? Considerable insight into the genetic basis of sporadic skin cancers has come from the elucidation of specific genes or genetic loci that define hereditary skin tumor syndromes (Table 110-2).[23] In particular, the importance of DNA as a target for carcinogenesis was strongly supported by the discovery of defects in DNA repair genes that comprise the complementation groups of skin-cancer-prone xeroderma pigmentosum (XP) families.[24,25] (see Chaps. 109 and 140). At least six independent genes on distinct chromosomal loci define proteins involved in nucleotide excision repair, a process critical for the protection of DNA against both UVR and chemical carcinogen-induced damage.[26] Among these are proteins that recognize and bind to sites of DNA damage (XPA, XPC, XPE), helicases (XPB, XPD), and endonuclease components (XPG, XPF), defects in any of which give a skin-cancer-prone phenotype. Potential polymorphisms with functional consequences in these and other DNA repair genes may contribute to susceptibility states in the general population as well.[27–29] Examination of SCCs and BCCs from XP patients has also revealed potential target genes for cancer induction because signature mutations in patched homolog 1 (48' ,), 6%7, T , and -2/ E%6* (alternative reading frame) have been found with high frequency.[30] Chromosomal mapping studies in the basal cell nevus syndrome (see Chap. 116), coupled with genetic and functional studies in (\VSTLME and mice, implicated mutations in the 48' , gene and other defects in the Hedgehog (Hh) signaling pathway in the development of hereditary and sporadic BCCs,[31] and a variety of internal malignancies.[32] All of these tumors are characterized by heightened levels of Hh signaling activity. The -2/ E%6* locus, specifically mutations in the -2/ %gene, was identified in the etiology of melanoma[33] through mapping of the inheritance pattern of familial melanoma. Detection of specific mutations in Cowden syndrome [phosphatase and tensin homolog (48) 2)],[34,35] Muir-Torre syndrome [mutS homolog 2 (1 7,), mutL homolog 1 (1 0,)],[35,36] multiple cylindroma [cylindromatosis (' =0( )],[37] multiple trichoepithelioma [cylindromatosis (' =0( )],[38] Birt-Hogg-Dubé syndrome [folliculin (*0' 2)],[39] sporadic pilomatricomas [β-catenin (' 82 2 &],[40] and sebaceous tumors [lymphoid enhancer-binding factor 1 (0) *)][41] have illuminated genetic defects associated with the development of adnexal tumors. The delineation of the specific genes mutated in other syndromes where locus mapping is confirmed (see Table 110-2) should provide even more insight into the molecular pathogenesis of a broader spectrum of skin neoplasms.

ANIMAL MODELS VERIFY THE GENETIC BASIS FOR CUTANEOUS NEOPLASMS

Using human hereditary cancer syndromes as a guide, genetically based animal models have been developed that validate the contribution of individual genes to human cancer susceptibility by prospective experimental analysis.[42] These models have also contributed to the un-

TABLE 110-2
Gene Targets for Mutations in Hereditary and Sporadic Cutaneous Cancers

GENE	FUNCTION	LOCUS	TUMOR TYPE	SYNDROME	SPONTANEOUS
P53	DNA repair, apoptosis, cell cycle regulation	17p13.1	BCC, SCC	Li-Fraumeni (but no increase in skin cancers)	Yes

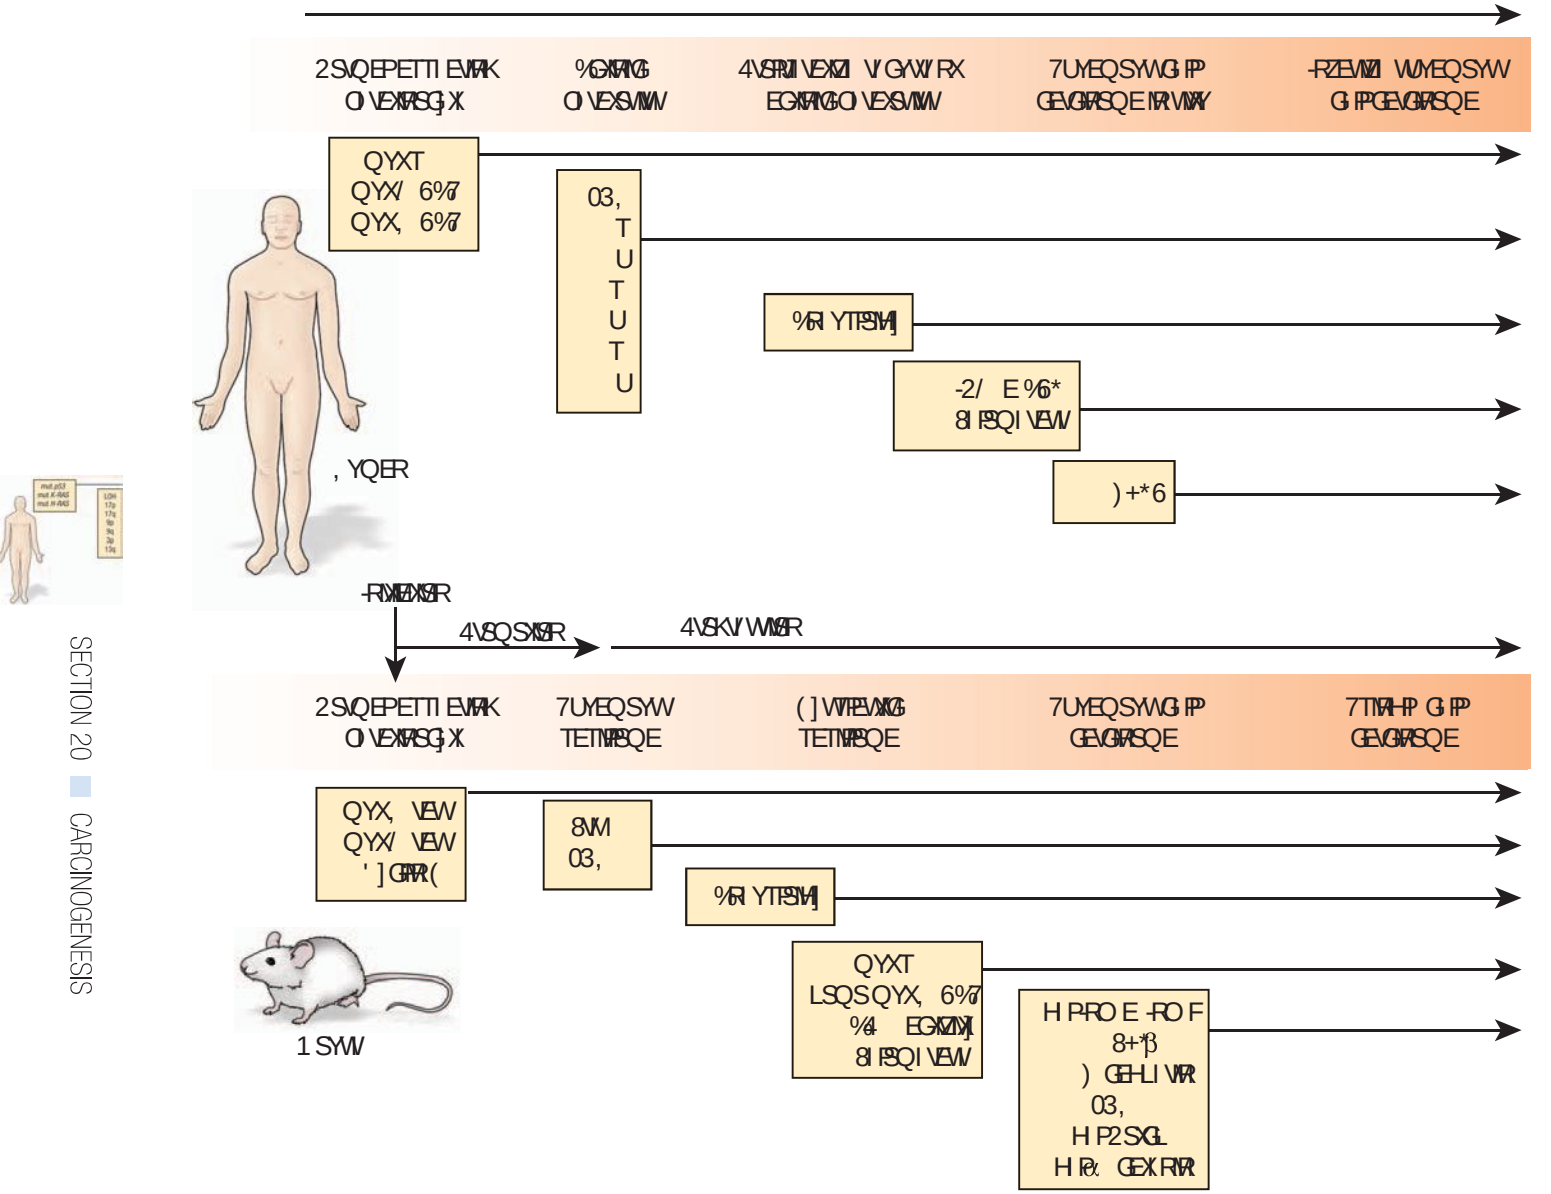
derstanding of gene–environment interactions by testing the influence of chemical and physical carcinogens on tumor development in the setting of an altered genetic makeup. The discovery of inactivating 48' , mutations and activating smoothened homolog (71 3) mutations in BCCs led to the development of several mouse models exploring the role of deregulated Hh signaling in BCC tumorigenesis.[31] Keratinocyte-targeted overexpression of sonic hedgehog (SHH)[43,44] or an activated form of the Hh pathway signaling molecule SMO (M2SMO)[45,46] resulted in the development of basal cell–like proliferations or follicular hamartomas in mouse skin. Overexpression of SHH in human keratinocytes grafted onto severe combined immunodeficiency mice also resulted in BCC-like lesions.[47] Mice with heterozygous disruption of the 48' , gene have features in common with basal cell nevus syndrome patients,[48,49] including microscopic hair follicle–derived tumors and various macroscopic skin tumors, including BCCs, after treatment with UVR or ionizing radiation.[50,51] When GLI1 or Gli2 transcription factors, which are nuclear effectors of Hh signaling, are targeted to mouse keratinocytes, multiple skin tumors develop. GLI1 mice display a variety of follicle-derived tumors with relatively few BCCs,[52] whereas Gli2 mice develop BCCs exclusively.[53] Interestingly, when Gli2 expression was extinguished in gene-switch mice, BCCs regressed but left behind a subset of residual tumor cells, at least some of which may be able to form growing tumors when the Hh pathway is re-activated.[54] Collectively, these findings provide strong evidence supporting the notion that constitutive Hh signaling plays a key role in, and may be sufficient for, BCC development.

The multistage induction of cutaneous SCC (Fig. 110-1)[55] and the absence of a hereditary syndrome that specifically imparts uniquely high susceptibility to this lesion have made the delineation of specific genetic loci involved in SCC induction more complex. Nevertheless, the analysis of genetic defects in human SCCs has focused attention on specific targets such as DNA repair genes, 6%7, T , T (-2/ %, and the epidermal growth factor receptor (EGFR) pathway. Significant progress has been made in defining pathways capable of driving NMSC development using reconstructed human skin, comprising genetically altered primary human keratinocytes on architecturally intact dermis, grafted onto immunedeficient mice.[56] Using this powerful system for modeling human skin cancer in mice, it has been shown that co-



▲ *-+96) Genetic changes associated with development of cutaneous squamous cell carcinomas (SCCs) in humans and mice. The multistage evolution of invasive SCC in humans is depicted schematically with frequently associated genetic changes. Single base mutations in early lesions frequently are characteristic of ultraviolet light–induced damage, whereas later changes are associated with genomic instability. Increased activity of telomerase (deletion of inhibitor) or epidermal growth factor receptor (EGFR) tyrosine kinase (gene amplification) may also result from epigenetic changes. In chemically induced mouse cutaneous SCC, the multistage evolution to spindle cell tumors in this model is highly ordered both temporally and genetically. Operationally defined stages include initiation, promotion, and progression. *Ras* mutations are characteristic of chemical mutagens used to initiate tumor formation. Early upregulation of cyclin D1 and later upregulation of transforming growth factor-β1 (TGF-β1) occur through epigenetic mechanisms and appear to be important components of carcinogenesis. Note that though *p53* alterations are seen at early stages of human SCC development and ultraviolet radiation–induced mouse SCC development (not shown), *p53* mutations occur at later stages during mouse chemical carcinogenesis. AP-1 = activator protein 1; LOH = loss of heterozygosity; mut = mutant. (Modified from Dlugosz A, Merlino G, Yuspa SH: Progress in cutaneous cancer research. *J Investig Dermatol Symp Proc* :17, 2002, with permission of Nature Publishing Group, London, U.K.)

expression of oncogenic Ras and either cyclin-dependent kinase 4 (Cdk4) or the nuclear factor κB inhibitor, I-κB, in human keratinocytes rapidly leads to invasive SCC development in reconstructed skin grafts.[57,58]

Mouse models for XPA, XPC, and XPE deficiency have been constructed, and all show sensitivity to UVR and enhanced development of SCC after either UVR or chemical carcinogen exposure.[25] A number of other DNA repair–deficient mutant mice are also being tested for cancer susceptibility and may reveal the mechanistic basis for new clinical syndromes by reverse genetics.[59] Mouse mutants targeting the 6EW gene have revealed important information concerning the contribution of the Ras pathway to particular stages of SCC development. Heterozygous activating 6EW gene mutations are sufficient to induce a benign squamous papilloma, the precursor to SCC, and the yield of chemically induced tumors in mice genetically deleted in the , \EW allele is markedly reduced.[60] Homozygosity of a mutant \EW

gene is associated with progression to SCC,[61] suggesting that high penetrance of the Ras pathway can recruit additional changes required for progression. Transgenic targeting of oncogenic 6EW6 suprabasal epidermis produces terminally benign tumors while mosaic targeting to basal cells or hair follicle outer root sheath cells encourages progression to SCC,[62] indicating the target cell for early mutations may also determine the tumor phenotype.[63] Although heterozygous p53 inactivation is detected early in human SCC, p53 deletion in mice enhances malignant progression but does not increase benign tumor formation.[64] This may be analogous to the common loss of heterozygosity seen at the T locus later in human SCC development.[65] Of particular interest for human tumor development is the frequent observation that double heterozygotes for p53 deletion and other cancer prone phenotypes (such as DNA repair deficiency) further sensitize mouse skin to tumor induction by UVR or chemical carcinogens. Mice with genetically defined defects in the T^{6Ink4a} locus or its downstream target Cdk4 are sensitive to both squamous tumor and melanoma induction after treatment with carcinogenic chemicals, consistent with defects in this pathway detected in both melanoma and non-melanoma human skin cancers.[66,67]

TUMOR BIOLOGY AND BIOCHEMISTRY

General Principles

Malignant tumors exhibit fundamental alterations in behavior that distinguish them from the normal tissues in which they arise. These differences include a reduced requirement for growth stimuli, impaired response to growth inhibitory/differentiation signals, alterations in apoptosis, delayed or blocked senescence, prolonged angiogenesis, and the capacity for invasion and metastasis.[68] Although one or more of these abnormalities can be detected at different stages of tumor progression and may thus be seen in pre-malignant lesions, all are present in advanced cancers. The driving force behind many of these changes is genomic instability, which facilitates the accumulation of mutations in both oncogenes and tumor suppressor genes that contribute to the observed aberrations in cell function.[69] Although some of these changes are cell-autonomous and can be studied in purified populations of tumor cells, others depend on various additional cell types recruited to participate in the development and progression of cancer in intact organisms. Both the intrinsic alterations in neoplastic keratinocytes and the influence of collaborating cell types in skin tumor biology are being elucidated through the use of powerful experimental models.

From analyses of both human SCC pathogenesis and experimental skin tumor induction by chemical carcinogens, specific pre-malignant and malignant stages have been identified that have typical phenotypic, genetic, and biochemical characteristics (see Fig. 110-1).[70,71] Note that in contrast to SCCs and most other cancers, BCCs do not appear to have precursor lesions or give rise to more aggressive cancers. This is likely related to the observation that the genomic instability that fuels neoplastic progression in other tumor types is largely missing in BCCs, even though a substantial proportion of these tumors harbor p53 mutations that would be expected to facilitate the accumulation of additional genetic defects. SCC starts as a single or small number of specific mutations in a cell that has the capacity to cycle, a change understood as the "initiation" of carcinogenesis. On clonal expansion, initiated cells form a pre-malignant lesion, such as a squamous papilloma in the mouse and an actinic keratosis in the human. Agents that enhance clonal expansion of initiated cells are called XYQSVTVSQSKWV Tumor promotion may occur as a consequence of exogenous exposures such as UVR, topical chemicals, medications, infections, or wound healing. Promotion may be an endogenous process influenced by diet, smoking, or immune suppression. The acquisition of additional mutations that provide a growth advantage to the incipient cancer cell may also serve as an autonomous promoting stimulus. Pre-malignant lesions undergo further phenotypic changes, often in a predictable sequence and commonly multifocal within a single lesion.[72] Some foci or lesions progress at a faster rate than others, and these are at highest risk for malignant conversion.[73] Pre-malignant progression encompasses the majority of the tumor latency period before malignant conversion, when the lesion shows invasive properties.

Initiation is usually a low-frequency genetic event and is directly dependent on carcinogen dose. A large variety of carcinogen classes can initiate skin tumors in rodents (Table 110-3). The phenotype of initiated epidermal cells as defined from in vitro analysis includes a defect in maturation, escape from senescence, and an enhanced growth poten-

Documented activity of these agents in rodent carcinogenesis models does not necessarily indicate that they also contribute to skin cancer development in humans.

tial, but initiated cells are still responsive to negative regulation, for example by transforming growth factor-β (TGF-β). At the molecular level, initiation involves an alteration in signal transduction pathways that regulate cellular responses to extracellular signals, and these are internally regulated by proto-oncogenes and tumor suppressor genes.[68,74] Tumor promotion is generally a non-genotoxic stimulus that results in a disturbance of tissue homeostasis.[72] Multiple classes of agents have promoting properties in experimental skin carcinogenesis (see Table 110-3). The mechanisms of tumor promotion include activation of cell surface receptors, activation or inhibition of cytosolic enzymes and nuclear transcription factors, stimulation of proliferation, inhibition of apoptotic cell death, and direct cytotoxicity. Genotoxic carcinogens also can have promoting properties, and repeated exposures to low concentrations of genotoxic carcinogens can induce tumors more effectively than fewer exposures to the same total dose in experimental carcinogenesis.[75] Exogenous tumor promoters can determine the target site for tumor formation, and the promoting action of UVR may in part contribute to skin targeting for tumors when germline mutations produce an initiated state in multiple cell types. In general, initiated cells respond differently to promoters than normal cells, allowing for clonal selection of an initiated population.[76] Pre-malignant progression in an initiated cell clone occurs spontaneously but is accelerated by additional exposures to genotoxic agents, including some cancer chemotherapeutic drugs.[77] Pre-malignant progression in chemically induced mouse skin carcinogenesis is associated with nonrandom, sequential chromosomal aberrations, including amplifications, duplications, deletions, and loss of heterozygosity,[78] suggesting repeated episodes of cell selection, producing specific chromosomal aberrations that become modally dominant within the progressing focus. Thus, at least one function of the relevant genetic events in pre-malignant progression must result in a growth advantage for the affected cell. Epigenetic changes are also associated with malignant conversion, and upregulation of activator protein 1 (AP-1) transcriptional activity, alterations in cell cycle regulatory genes and secreted proteases, changes in gene splicing, and expression of modified cell surface molecules have all been reported. Together, these changes could facilitate migration and invasion that characterize the malignant phenotypes.

TABLE 110-4
Animal Models of Cutaneous Cancer Induction by Exogenous Agents

AGENT	SPECIES	COMMENTS
&EVWEP IPP EVGWSQE		
3-Methylcholanthrene	Rat	Other skin tumors
DMBA	Rat	SCC > BCC; lower DMBA doses may increase BCC incidence

Ultraviolet A	Mouse	Papillomas and SCC

AA = aromatic amines; BCC = basal cell carcinoma; DMBA = 7,12-dimethylbenz[a]anthracene; NA = nitrosamines; PAH = polycyclic aromatic hydrocarbons; SCC = squamous cell carcinoma.

Alterations in methylation of DNA in tumor cells could also contribute to this stage of carcinogenesis.[79]

Pathogenesis of Basal Cell Carcinomas

Animal models for induction of skin tumors by chemical and physical agents have been extremely valuable for exploring mechanisms of carcinogenesis in an experimental setting (Table 110-4). Rats exposed to chemical carcinogens (methylcholanthrene, dimethyl benzanthracene) or ionizing radiation preferentially develop BCCs[80] that are phenotypically similar to human BCCs. In contrast, mice are resistant to BCC induction in the absence of genetic modification, although one study described mouse BCC development following either subcutaneous or topical exposure to dehydroretronecine,[81] an observation that has not been explored mechanistically.

As noted in General Principles, BCCs represent an intriguing exception to the rule of multistage cancer development. Individual tumors typically consist of homogeneous, slowly growing cells that very rarely metastasize, although they can cause extensive local damage (see Chap. 115). Even those rare BCCs exhibiting cellular atypia generally have a benign course,[82] suggesting that the full complement of factors driving malignant progression in SCCs and other neoplasms is not operating in these tumors. BCC cells exhibit abnormalities in growth control and terminal differentiation, induce clinically apparent angiogenesis, and invade their immediate surroundings. However, transplantation studies using human BCCs or transgenic mouse skin with BCC-like lesions[43] suggest that the tumor cells are critically dependent on adjacent stroma for survival. This property may help explain both the lack of BCC metastases and the difficulty in establishing BCC cell lines. Interestingly, in a recent study in which global gene expression profiling was performed on stromal cells derived from tumors versus normal tissue, the bone morphogenetic protein (BMP) antagonist, GREMLIN 1, was found to be highly expressed in BCC stroma but not normal skin.[83] BCCs express BMP 2 and 4, and GREMLIN 1 stimulates growth of cultured BCC cells in vitro, suggesting that GREMLIN 1 may be a key stromal factor needed to support BCC proliferation in vivo, by antagonizing growth-inhibitory effects of BMPs.

Studies performed using human and rodent BCCs have identified additional candidate molecules that may be important in the biology of these tumors. Upregulation of various matrix metalloproteases (MMPs), both in tumor cells and stroma, is likely to be important in the local invasion of BCC and may impact on growth control and other cellular functions given the emerging role of MMPs in regulating signaling at multiple levels.[84] Expression of several adhesion molecules is downregulated in BCCs, and this may account for the characteristic appearance of artifactual clefts between tumor cells and stroma in histologic sections, but the functional significance of this finding in BCC biology has not been established. The anti-apoptotic molecule BCL2 is consistently upregulated in BCCs probably because &' 0 is an Hh target gene, but this does not appear sufficient to block apoptosis in these tumors as it does in other set-

tings. Indeed, the remarkably slow growth rate of BCCs has been attributed in part to baseline apoptotic cell loss. Expression studies in human BCCs and experimental models suggest the involvement of growth factor signaling pathways such as platelet-derived growth factor[85,86] and EGFR.[87] Several lines of evidence point to components of the cell cycle machinery as potentially critical targets in mitogenic responses to Hh signaling. Keratinocytes overexpressing Shh have enhanced proliferative potential and fail to undergo growth arrest in response to the cell cycle inhibitor p21[88]; in the absence of Shh, Ptch1 interacts with and may sequester cyclin B1, which is required for mitosis and cell cycle progression[89]; and Shh can drive proliferation of immature cerebellar cells by causing prolonged induction of cyclins D1, D2, and E.[90] In skin, Hh-driven proliferation of hair follicle epithelium is likely to be mediated by cyclin D2 and N-Myc.[91] As additional Hh target molecules are uncovered, their potential involvement in keratinocyte tumor biology can be tested using mouse models of BCC that are currently available.

Pathogenesis of Squamous Cell Carcinomas

In addition to deregulated growth control, there is a progressive loss in the capacity for terminal differentiation during SCC progression (see Fig. 110-1), culminating in a tumor with a spindle cell morphology that is indistinguishable from malignancies originating in mesenchymal tissues. Although the mechanisms responsible for defective differentiation at different stages of human skin cancer are not known, there is evidence that deregulation of the protein kinase C (PKC) family of enzymes plays a role in aberrant differentiation of mouse skin keratinocytes expressing the Ras oncogene.[72] PKCδ, which has been implicated in terminal differentiation of normal epidermal keratinocytes, is rendered inactive as a result of tyrosine-phosphorylation in ras-transformed keratinocytes. Restoring PKCδ to its native, non-tyrosine phosphorylated state reversed the block to terminal differentiation in ras-transformed keratinocytes. In addition, overexpression of PKCδ in the skin of transgenic mice inhibits the development of squamous papillomas and carcinomas.[102] In contrast, skin-targeted overexpression of PKCε resulted in less differentiated SCCs that rapidly metastasized to regional lymph nodes.[103] Additional work is needed to better understand the mechanism by which SCC tumor cells evade signals that trigger differentiation of normal keratinocytes.

Prostaglandin metabolism is activated by UVR and is constitutively induced in human SCCs, probably due to overexpression of the enzyme cyclooxygenase 2 (COX-2). Although the mechanism by which changes in prostaglandins influence skin cancer is not clear, they appear to operate at the tumor promotion stage. Telomerase activity is detected in a substantial proportion of human skin cancers, suggesting that these tumor cells are capable of evading cellular senescence, and telomerase-deficient mice are resistant to chemical carcinogenesis.[104] Additional contributors that are likely to be involved in SCC development and progression include mediators of angiogenesis, MMPs, and integrins, as well as other molecules involved in cellular adhesion and migration.

Spontaneous or carcinogen-induced tumor formation on genetically modified mice has revealed genes and pathways that appear to be important in skin cancer induction but would not have been apparent from hereditary cancer syndromes or analysis of human skin cancers. Suprabasal targeting of C-myc in transgenic mice permits suprabasal cells to cycle and produces the papilloma/actinic keratosis phenotype while basal cell targeting of C-myc is not oncogenic.[105,106] Deletion of the cyclin/CDK inhibitor p21[waf1], a downstream effector of p53, increases the number of benign tumors but not the rate of pre-malignant progression.[107,108] TGF-β suppresses pre-malignant progression but is required for progression from SCC to a spindle cell phenotype.[109–112] Two AP-1 transcription factors influence distinct stages of skin tumor development, where c-Jun is essential for papilloma and c-Fos is essential for SCC development.[113,114] Inhibition of AP-1 activity in benign papillomas prevents progression to carcinomas, but instead converts these lesions into benign sebaceous adenomas,[115] supporting the concept that squamous tumors are derived from progenitor cells with multilineage potential. Additional molecules now implicated in SCC development are ornithine decarboxylase, p16[Ink4a], p15[Ink4b], E-cadherin, STAT3, C-myc, Notch, α-catenin, nuclear factor kappa B, and Smad3.[116–124]

Constitutional Modifiers of Carcinogenesis

Inbred mouse strains differ in susceptibility to particular carcinogenic exposures by several orders of magnitude, and transplantation studies indicate sensitivity resides in the target tissue rather than systemically. Genomic scans of backcrossed mice among sensitive and resistant mouse strains indicate that constitutional determinants are multigenic and distinct for benign tumor formation or progression.[125,126] Similar studies indicate genetic loci determine the survival potential for tumor bearing animals.[127] Although the classical genetic approaches are frequently difficult and complex because multiple interacting loci are likely to be involved,[128] use of these methods to identify genes involved in susceptibility and resistance in animal models is likely to reveal determinants important for human skin cancer risk. For example, the identification of a susceptibility gene for mouse skin cancer, Aurora2 (7XO), led to the discovery of a variant of the homologous human gene (78/) that is likely to contribute to cancer development in the colon[129] and other organs.[130] These reports underscore the power of this experimental approach and the concept that studies in skin may be highly relevant to understanding tumorigenesis at other sites, because common mechanisms underlie cancer development in different organs.

Analysis of genetically modified mouse models has also revealed pathways associated with skin tumor susceptibility. Alterations in p53,[64] drug metabolizing enzymes,[131] T-cell function,[132] and DNA repair[59] modify risk for experimental skin cancer induction. Remarkably, polymorphisms in drug metabolizing enzymes and DNA repair pathways,[133,134] and variable responses in the p53 tumor suppressor pathway or in T-cell immunity after exposure to skin carcinogens[135,136] modify the human risk for skin cancer.

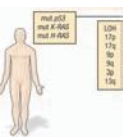
Exogenous Modifiers of Carcinogenesis

In experimental models, antioxidants and agents that alter microsomal metabolism of carcinogens can reduce or prevent tumor initiation by inhibiting the formation of ultimate carcinogens or accelerating their detoxification (Table 110-5). Similar mechanisms may influence ultraviolet light or ionizing radiation mutagenesis through inhibition of mutagenic oxyradicals produced endogenously following exposure. Scavengers prevent reactive mutagens from reaching critical targets. Cell cycle in-

TABLE 110-5
Modifiers of Carcinogenesis

Inhibitor Class	Examples
Inhibitors of initiation	
Antioxidants, scavengers	Butylated hydroxyanisole; butylated hydroxytoluene; selenium; vitamin C; vitamin E; ellagic acid
Inducers of mixed function of oxidase	Polycyclic aromatic hydrocarbons; TCDD; PCB
Inhibitors of mixed function oxidase	α-Napthoflavone; glucocorticoids
Cytotoxic agent	Sulfur mustard
Suppressor of tumor development	Retinoids
Inhibitors of promotion	
Antiproliferative	Anti-inflammatory steroids: dexamethasone, fluocinolone acetonide; inhibitors of arachidonic acid metabolism: indomethacin, celecoxib; inhibitors of polyamine metabolism: α-difluoromethylornithine
Antioxidant	Antioxidants: tert-butylhydroxyanisole, selenium; protease inhibitors: leupeptin, tosyl lysine chloromethylketone; superoxide dismutase; copper (II) 3,5-diisopropylsalicyclic acid
Natural products and dietary factors	Retinoic acid; vitamin D; green tea; silymarin; resveratrol; ursolic acid; caffeic acid phenethyl ester; curcumin; 1,25-dihydroxyvitamin D_3

PCB = polychlorinated biphenyl; TCDD, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin.



hibitors prevent fixation of mutations, allowing for DNA repair while cytotoxic agents kill initiated cells before their expansion into a tumor mass.

A number of agents are effective in the post-initiation phase of experimental tumor development, and some are being clinically evaluated.[137] Inhibitors of COX-2 (celecoxib, indomethacin) and ornithine decarboxylase (difluoromethylornithine) prevent both UVR and chemically induced tumors.[138,139] Although the mechanism of action of retinoids as modifiers of tumor development is not clear, retinoids are effective inhibitors of benign tumor formation in mouse skin carcinogenesis studies and show promise as inhibitors of actinic keratoses and cutaneous tumors in human studies. Predictable and parallel alterations in retinoid receptors in mouse and human cutaneous SCC indicate that the retinoid pathway must be central to cancer development in epidermis.[140,141] Considerable interest has developed in dietary factors that modify skin carcinogenesis. Restricted fat/energy diets reduce papilloma incidence in mouse models[142] and decrease the frequency of actinic keratoses in human populations.[143] Diverse dietary or natural factors, such as green tea, caffeic acid phenethyl ester from honey bee hives, resveratrol from grapes, silymarin from milk thistle, ginger extract, crocetin, and ursolic acid from the rosemary plant, are among natural products shown to be effective inhibitors of skin tumor formation by topical application or systemic exposure.[144] Several of these agents are believed to be antioxidants, but the precise mechanism of inhibition and their effectiveness as chemopreventive agents for human skin cancer remain to be established. Finally, immune response modifiers, such as imiquimod, may be effective for treating some types of skin cancer by modulating cytokine expression.[145]

NOVEL MOLECULAR TARGETS BASED ON NEW MECHANISTIC DATA

The substantial progress in our understanding of factors involved in skin tumor pathogenesis holds the promise of new approaches to treatment and prevention. In addition to the identification of new therapeutic targets, improved strategies are being developed for altering gene and protein function in skin with great selectivity. The abundance and unrivaled accessibility of skin cancers and pre-cancers makes them prime targets for rigorous translational studies and clinical trials. Based on the basic research studies outlined in this chapter, potential therapeutic targets include p53; COX-2; telomerase; EGFR or other receptor tyrosine kinases, and intracellular signaling elements such as SOS; Ras; ornithine decarboxylase; the DNA repair machinery; MMPs; PKC; molecules involved in cell cycle progression, such as cyclins D1 and D2, CDK4, $p^{16INK4a}$, and E2F1; retinoid receptors; and c-Fos. In all cases, the potential efficacy of the proposed treatments would need to be carefully evaluated in animal models or human tissues grown in immune-deficient mice. Because the great majority of cutaneous SCCs are effectively treated using surgery or radiation therapy, perhaps the greatest utility of these studies for dermatology patients would be in the identification of agents capable of preventing the appearance of pre-malignant lesions or blocking neoplastic progression to SCC in predisposed individuals. Along these lines, a double-blind study reported a significant reduction in the development of actinic keratoses and BCCs in XP patients treated topically with the DNA repair enzyme T4 endonuclease V, administered over a 1-year period.[146]

In contrast to the multiple genetic and biochemical changes associated with SCC development, the majority of BCCs have mutations in 48' , or 71 3, and essentially all of these tumors exhibit uncontrolled activation of the Hh pathway. Because several experimental models suggest that deregulated Hh signaling plays a central role in BCC development and maintenance, this pathway is a prime target for mechanism-based drug development. Cyclopamine and related molecules block Hh signaling by inhibiting SMO function,[147] and have been shown to inhibit growth of BCC-like tumors[148,149] and other "Hh-activated" tumors in pre-clinical studies.[150,151] However, Hh is a crucial embryonic signaling pathway[152] whose inhibition causes profound developmental defects, so attempts to treat or prevent human BCCs by modulating this pathway will need to be approached with care. Given the recent advances in our understanding of NMSC, it seems likely that new, rationally designed medical approaches for intervention will soon be available for these common neoplasms.

This chapter discusses major viruses implicated in skin cancer (Table 111-1), the evidence of their role, what is known about their mechanism of action, and how they can be controlled by preventive and/or therapeutic approaches.

INTRODUCTION TO ONCOGENES AND TUMOR SUPPRESSOR GENES

Studies looking at the mechanisms by which viruses induce tumors discovered oncogenes critical for cell transformation. Oncogenes derive from normal cellular genes referred to as TVSSRGSKIRIW that encode for various proteins involved in positive control of cell proliferation, such as growth factors, growth factor receptors, signal transduction proteins, and transcription factors.[1] These genes were first identified by studying retroviruses in animal models.[2] Retroviruses belong to the class of RNA viruses and convert their genetic information into DNA after infection of the host cell. Later, the human counterparts of retroviral oncogenes were recognized. Other retroviruses lack their own viral oncogene but integrate their viral DNA near a proto-oncogene, leading to its deregulated expression. It has been recognized for some time that retroviruses acquired their viral oncogenes by their capacity to integrate into and then be excised from the DNA of the host cell, allowing the virus to pick up and modify cellular genes through amplification, mutation, and deletion, thus converting them into transforming genes when reintroduced back into a host cell. The oncogenes of retroviruses derive from genes that are highly conserved in evolution. Deregulation of one or more proto-oncogenes, rendering them constitutively active, occurs in a wide variety of human and animal tumors, regardless of etiology.

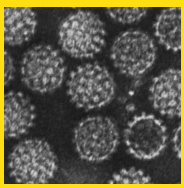
In contrast to retroviruses, DNA viruses contain oncogenes that are not derived from cellular proteins. Examples include the epidermal growth factor homolog of pox viruses or the middle T antigen of polyomavirus that can activate proteins encoded by cellular proto-oncogenes. Large DNA tumor viruses have genes with cellular homologues, but small DNA tumor viruses have instead small multifunctional proteins with no cellular homolog.

Other genes identified initially from genetically susceptible cancer-prone patients or family cancer syndromes, such as retinoblastoma (Rb)[3] or Li-Fraumeni syndrome (p53), have been characterized and are called XYQSV WTTVWWSV KIRIW The physiologic role of these genes is to negatively control cell growth. Studying the relationship of

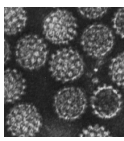
TABLE 111-1
Virus-Associated Cancer in Humans

VIRUS GROUP	VIRUS	CANCER
Hepadnavirus	Hepatitis B	Hepatocellular carcinoma
Hepadnavirus	Hepatitis C	Hepatocellular carcinoma
Herpesvirus	Herpesvirus type 4 (Epstein-Barr virus)	Burkitt lymphoma, nasopharyngeal carcinoma
Herpesvirus	Herpesvirus type 8	Kaposi sarcoma lymphoma
Papillomavirus	Oncogenic types, especially 5, 8, 16, 18, 31, 33, 35, 58	Cervical, vulval, vaginal, penile, and anal carcinoma; cutaneous squamous skin carcinoma in epidermodysplasia verruciformis, and perhaps other non-melanoma skin carcinomas
Retroviruses	Human T-cell lymphotropic virus type 1, human immunodeficiency virus	T-cell lymphoma and leukemia
Simian virus	SV40	Ependymoma, plexus choroid tumors, mesothelioma, bone tumors

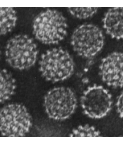
VIRUSES AND CANCER AT A GLANCE



- At least 10 percent to 15 percent of human cancers are induced by viruses. Viruses may directly induce malignancy via introduction of a viral oncogene or inactivation of a host tumor suppressor gene.
- Iatrogenic immunosuppression, solar irradiation, or other factors may cooperate with viral infection to cause malignancy.
- Viral vaccines may reduce the incidence of specific cancers.



specific tumor suppressor genes with certain viral proteins increased greatly the knowledge of how viruses can be implicated in cancer in general and more particularly in skin cancer. For example, the large T antigen of SV40 virus or the E1A and E1B proteins of adenoviruses and, of more importance in dermatology, the E6 protein of oncogenic human papillomaviruses (HPVs), bind to and functionally inactivate cellular tumor suppressor genes, turning off the physiologic negative control of cell growth, thus promoting cell transformation.



VIRUSES IN DERMATOLOGIC TUMORS

Human Papillomaviruses (See Chap. 196)

, 91 %2 4%4-0031 % -697 7869' 896) %2(1)' , %2-71 7 3* % 8-32 -2 86%27*361 % 8-32 HPV can be categorized according to sequence variations in E1, L1, E6, and E7 viral genes.[4] To date, more than 120 HPV types have been characterized and classified into five subgroups—A, B, C, D, and E—with differing host specificity, tissue tropism, and oncogenic potential. A and B families include mucosal and cutaneous HPV types. A and B families include mucosal and cutaneous HPV types. These two families contain both high-risk HPV, such as mucosal HPV-16, -18, -31, -33, -35, and -58, as well as HPV-5 and -8 associated with epidermodysplasia verruciformis (EV), and low-risk HPV found in benign condyloma (HPV-6, -11) or common cutaneous viral warts (such as HPV-1 and -2).

In vitro studies have allowed the demonstration of the transforming role of E6 and E7 proteins of high-risk HPVs, particularly those of mucosal viruses. In anogenital lesions, HPV DNA is often found in an episomal state in benign lesions and is frequently integrated in invasive lesions. This integration may play a role in transformation, as it frequently disrupts the coding sequences of E1 and E2 genes. Because the E2 transcriptional regulator binds to cognate recognition sequences in HPV promoters to regulate expression of the E6 and E7 genes, its disruption can lead to dysregulated E6 and E7 expression.

The transforming property of the E7 protein of high-risk HPV was the first to be demonstrated. E7 binds a member of the Rb family, p105Rb, which dissociates p105Rb-E2F complexes by inducing proteosomal degradation of p105Rb and liberates transcription factors involved in the beginning of the cell cycle.[5] Interestingly, it has been shown that substitution of a single amino acid in the E7 protein, affecting its ability to bind and degrade Rb protein family members, could explain the difference in transforming capacity of E7 between high- and low-risk HPV.[6,7]

The E6 protein of high-risk HPV is also implicated in transformation. It was first demonstrated that cooperation between the E6 and E7 protein was more efficient in inducing cell transformation than either protein alone.[8]

The first target of the E6 protein that was identified was the p53 tumor suppressor gene protein, a key regulator of the cell cycle often referred to as the "guardian of the genome." It was demonstrated that the E6 protein of high-risk mucosal HPV is able to induce p53 degradation through its association with an E3 ubiquitin ligase of the HECT (homologous to E6-AP carboxyl terminus) domain family known as) %4[9,10] The degradation of p53 abolishes the p53-dependent induction of cell cycle arrest or apoptosis. Thus, elimination of p53 allows HPV-infected cells to escape apoptosis, thus providing a background in which normal growth restraints are absent. Similar to the E7 protein, it has been shown that only the E6 protein of high-risk HPV but not that of low-risk HPV was able to degrade p53. Moreover, it has been shown that E6 can sequester the p53 protein in the cytoplasm, inactivating it without inducing its degradation.[11]

Additionally, HPV E6 proteins of cutaneous HPV types that, in marked contrast to anogenital viruses, do not promote p53 proteolysis are nevertheless able to inhibit p53-induced apoptosis. An additional anti-apoptotic activity of the E6 protein is its inhibition of the Bak protein, a key regulator of the mitochondrial apoptotic pathway (reviewed in ref. 12).

A cross-talk between the Rb and p53 pathways and the interaction of E6 and E7 proteins in both pathways add to the synergic role for E6 and E7 in cell transformation. Cooperation between E6 and E7 proteins and the ras family of oncogenes has also been shown. Other cellular targets are probably involved in the transforming capacity of E6 and E7 proteins.

Besides their role in the control of cell cycle key regulators, E6 proteins of high-risk HPV have been shown to play an important role in genomic stability and, more precisely, DNA repair. Skin cells expressing the high-risk HPV-5 E6 protein are defective in ultraviolet (UV) B–induced DNA damage repair.[13]

Transgenic animal models for HPV have also been generated. The first one was developed by Tinsley et al.[14] in 1992 by expressing the early gene region of HPV-1, inducing plantar warts under the K6 promoter. The transgenic murine skin showed epidermal hyperproliferation and abnormal keratinocyte differentiation. More recently, a transgenic mouse model was generated expressing the complete early region of EV-associated HPV-8 in basal keratinocytes under the control of the K14 promoter. Over 90 percent of the transgenic mice spontaneously developed benign skin tumors with significant conversion to squamous cell carcinomas (SCCs),[15] which is remarkable compared to many other HPV-transgenic mice previously developed.

HPV-associated skin diseases are frequent[4] and are discussed in more detail in Human Papillomavirus and Skin Cancers and Human Papillomavirus and Epidermodysplasia Verruciformis.[16]

, 91 %2 4%4-0031 % -697 %2(')6: -' %0 ' %2')6 The close relationship between infection with certain HPV types and the risk of developing cervical cancer was noted initially by zur Hausen in 1977[17] and later confirmed by many fundamental molecular and epidemiologic lines of evidence. It is now thought that 99.7 percent of invasive SCC of the cervix contain high-risk HPV types.[18] Cervical cancer is therefore the first tumor recognized to be almost exclusively virus-induced.[19]

Epidermoid cervical cancers are the major form of cervical cancer (80 percent to 95 percent) and represent a major public health problem, especially in developing countries.

The importance of oncogenic HPV in cervical cancer renders HPV typing an important clinical tool for the treatment and follow up of patients with HPV-associated cervical morphologic abnormalities.[20]

However, it is more the persistence of oncogenic HPV rather than its simple detection that is a major carcinogenic factor.[21,22] Viral load also seems to be important to consider, as the level of high-risk HPV-16 detected by quantitative polymerase chain reaction (PCR) is higher in severe dysplasia when compared to moderate or low dysplasia and even more when compared to normal tissue. However, the importance of the viral load remains controversial and awaits further clarification.

Numerous vaccine strategies have been developed and are currently under clinical application, particularly in countries and populations with high oncogenic HPV prevalence.[23] Prophylactic HPV subunit vaccines based on the ability of the viral L capsid protein to form virus-like particles inducing high levels of neutralizing antibodies have recently been approved by the U.S. Food and Drug Administration. The vaccines target both HPV-16 and HPV-18, between them accounting for approximately 70 percent of cervical cancers. The vaccines have an excellent safety profile, are highly immunogenic, and have conferred complete type-specific protection against persistent infection and associated lesions in fully vaccinated women. The key issues are the definition of the ideal target population and the cost of the vaccines, which need to be sufficiently low for widespread implementation in the developing world where 80 percent of cervical cancer occurs. Other considerations include the length of protection afforded by the current vaccines and whether observed cross-reactivity with other HPV types can be sufficiently protective to prove beneficial.

, 91%2 4%4-0031%-697%2(38,)6+)2 -8%0'%2')6 In external anogenital cancers (e.g., vulvar or penile cancer), the role of oncogenic mucosal HPV is also well established, and the same mechanisms of action in transformation as identified in cervical cancer are implicated. However, unlike cervical cancer, HPV is not the only carcinogenic factor involved in external anogenital cancers: the inflammatory dermatosis, lichen sclerosus (see Chap. 63), is also implicated. In HPV-derived external anogenital cancer, little or no mutation of cell cycle regulator genes, such as p53 and the $p^{16ink4-ARF}$ locus, is observed, whereas in lichen sclerosus–derived tumors, mutations of both pathways are common and may relate to the aggressive nature of such tumors.[24]

, 91%2 4%4-0031%-697%2(7/-2'%2 ')67 As with cervical cancers, HPV DNA is detected frequently in skin carcinomas of immunocompetent (30 percent to 35 percent) and immunocompromised (75 percent) individuals. However, many different HPV types have been found in these tumors, and no pattern of high-risk or low-risk HPV types has yet emerged for skin cancer. Furthermore, although HPV DNA is frequently detected in swab samples collected from the superficial layers of skin tumors, significantly less HPV DNA is found in incisional biopsies of the same tumors (reviewed in ref. 25), advising cautious interpretation. A possible explanation is that tape stripping would remove the outer epidermal layers that contain the productive viral infection and so might be expected to reduce the viral DNA present. Perhaps of more significance are in situ hybridization studies[26] and viral load studies, both of which find that detection of active viral infection in skin tumors is patchy and suggest that DNA detection studies may be overly sensitive and not necessarily a reliable reflection of active HPV infection. EV-associated HPV types (now termed β , 4: Ware also frequently reported in normal skin, in hair follicles, or even in benign dermatoses such as psoriasis. In both immunocompetent and immunosuppressed patients, the role of HPV in skin cancer remains controversial, but evidence for a viral role promoting the mutagenic effects of UV damage is increasing. The presence of β-HPVs may be considered a risk factor together with the pattern and amount of sun exposure, sun sensitivity (skin color), country of residence, and number of sunburning episodes. In immunosuppressed patients, the duration and type of immunosuppressive drugs used are important additional factors. Most recent studies confirm a prevalence of β-HPVs of 70 percent to 80 percent in organ transplant–associated SCC and approximately 30 percent of immunocompetent SCC (reviewed in ref. 27). In skin cancer, the typical high-risk mucosal HPV (HPV-16) is found only in in situ or invasive epidermoid periungual carcinoma (see Chap. 114). In that situation, the presence of high-risk HPV-16 is thought to be by contact with the genital area and is equivalent to a sexually transmitted disease state.

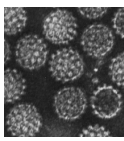
HPV-38 has been detected significantly more often in skin tumors (50 percent) than in normal skin (10 percent). Additionally, HPV-38 has been found in vitro to actively support immortalization of cultured human keratinocytes.[28] However, the importance of HPV-38 in skin tumor development awaits further elucidation.

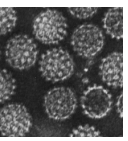
Overall, the role of HPV in skin cancer is still unclear, although a role in combination with UV radiation seems likely in the early stages of tumor development.

, 91%2 4%4-0031%-697%2( )4-()613 (=740%7-%:)669'-*361-7 (See Chap. 196) EV is a rare autosomal recessive disease characterized by an early onset and lifelong occurrence of multiple flat warts, pityriasis-like macular lesions, and occurrence of skin cancer, mostly on sun-exposed skin. EV-type HPV integration is rare in skin cancer except in metastases. Additionally, the E6 protein of EV HPV does not degrade p53, and its E7 protein has little transforming potential in vitro,[29] although the E7 gene of HPV-5, another β-HPV type, was shown to induce the invasion of keratinocytes into the dermis in a skin-equivalent model. The invasion was accompanied by the destruction of basement membrane components, most likely through the induction of specific matrix metalloproteinases.[30] The E6 protein of β-HPV may interact with the pro-apoptotic Bak protein to promote cell transformation, but this needs to be further understood.[12,16]

The first breakthrough in functional studies was the demonstration that a number of different HPV E6 proteins can effectively block the epidermal apoptotic response to UVR,[31] suggesting a mechanism whereby a diverse group of HPV types might promote tumor development in cooperation with the mutagenic effects of UVR. Corresponding in vivo studies have shown that the balance between proliferation and apoptosis is altered by HPV status: HPV-positive tumors have significantly reduced apoptotic rates compared to HPV-negative lesions,[32] apparently related to degradation of Bak.[33] Bak is located in the outer mitochondrial membrane and assembles into multimeric complexes during apoptosis, acting as a "gateway" to allow transit of apoptotic effector molecules, such as cytochrome c, thereby controlling initiation of the apoptotic cascade.[12]

Additional type-specific viral activities that interfere with the cellular response to UVR can be postulated. For example, keratinocytes expressing high-risk HPV-5 E6 protein, but not the E6 protein of benign cutaneous HPV types -10 and -77, take longer to repair UV-induced thymine dimers and therefore enter the cell cycle harboring such DNA damage, specifically bypassing the G1/S checkpoint[13] (see Chap. 112). Of the HPV types tested, only the cancer-associated HPV-5 E6 and not the E6 proteins of non–cancer-associated EV HPVs, such as types -23, -24, and -49, displayed this phenotype. Similarly, E6 proteins of HPV-1 and HPV-8 have been shown to interact with the XRCC1 protein that is involved in the repair of DNA single strand breaks.[34] Perhaps E6 can help cells overcome cell cycle checkpoints, allowing the propagation of UV-induced DNA damage that, in





turn, increases the likelihood of accumulating errors in key genes and the acquisition of genetic instability, both driving skin tumorigenesis in the context of continuing UV exposure.[16]

Two susceptibility loci have been identified in EV patients, on chromosomes 17q and 2. In the EV1 locus, Ramoz et al. identified two new genes, EVER1 and EVER2, in which mutation seems to segregate with the disease.[35] In unaffected individuals in whom EV HPV type can be found in normal skin, no mutation in EVER1 or EVER2 is found, and therefore no EV lesion is seen, whereas in EV patients bearing EVER1 or EVER2 mutations, EV lesions develop. The long splice isoforms of EVER1 and EVER2 are identical in sequence and genomic localization to the transmembrane channel–like (TMC) proteins TMC6 and TMC8.[36] Additionally, it has been shown that EV patients have a deficiency in cellular immunity against EV HPV, which adds another carcinogenic immunologic factor to explain transformation in such patients.[37]

Herpesvirus in Skin Tumors

, 91 %2 ,) 64) 7: -697 %2(/ %437- 7%6 ' 31 %%2(0=14, 31 %Kaposi sarcoma herpesvirus 8 (KSHV) or human herpesvirus 8 (HHV-8) is, together with Epstein-Barr virus, a member of the herpesvirus family known for its ability to induce neoplasia in natural or experimental hosts. Strong epidemiologic studies favored the role of a sexually transmissible agent involved in KS pathogenesis (see Chap. 128). It was only in 1994 that Chang et al.,[38] using representational difference analysis, identified two fragments of an unknown herpesvirus in a biopsy from an acquired immunodeficiency syndrome–related KS, soon to be classified as the first human 2-herpesvirus or rhadinovirus.

HHV-8 has evolved into five variants (A through E) that probably emerged after population migrations over the last 40,000 years. Such variants may have functional implications, although no association between variants and pathologies have been identified so far.[39,40] HHV-8 has a long unique region of approximately 145 kilobases, with at least 87 genes and a variable number of terminal repeats. Apart from genes involved in structure, virion maturation, DNA replication, nucleotide metabolism, and gene regulation, HHV-8 encodes for human gene homologues probably acquired from human cellular complementary DNA. Due to structural modifications, some of these pirated genes have become constitutively active and are oncogenes. After infection, HHV-8 remains in a latent state in the host cell (circular episomes), with minimal gene expression (latent genes). Lytic infection can occur in vivo and can be reproduced in vitro using pharmacologic agents such as histone deacetylase inhibitors.[41]

HHV-8 cellular homolog genes can be classified according to their biologic function as cell cycle regulators; stimulators of mitosis; anti-apoptotic, pro-angiogenic, immune-response inhibitors; and stimulators of transdifferentiation.[42]

, 91 %2 ,) 64) 7: -697 , 91 %2 ,) 64) 7: -697 %2(0%2+) 6, %27 ') 00 , -78-3' = 837-7 Langerhans cell histiocytosis (see Chap. 148) is a disease characterized by Langerhans cell infiltration of skin and bone, with sometimes severe and multifocal infiltration of many organs, in which case it is best considered a malignant disease. The role of HHV-6 has recently been proposed but remains unproved.[49,50] A recent study searching for an association of HHV-8 with Langerhans cell histiocytosis has failed to demonstrate a causal role of that virus.[51]

, 91 %2 ,) 64) 7: -697 %2(7/ -2 ' %2') 6 One study of the presence of HHV-6 and HHV-1 in DNA samples from 120 nonmelanoma skin cancers and 41 normal skin tissues showed that the risk for individuals with HHV-1 to have basal cell carcinoma and SCC was increased eight and six times, respectively. However, the small number of samples studied as well as the very high prevalence of HHV-1 infection in the normal population precludes firm interpretation of this correlation.[52]

VIRUS-DERIVED FUTURE STRATEGIC THERAPIES

Besides in vaccines such as those developed for "high-risk" HPV infections, the use of viral vectors has now expanded from relatively safe, non-replicating viruses to the use of viruses that replicate preferentially in cancer cells versus normal cells and belong to the so-called SRGSP XG ZMWVWV As these viruses replicate, they lyse their host cells. Cancer cells are ideal hosts for many viruses because they have inactivated the anti-viral interferon pathway or have mutated tumor suppressor genes, enabling viral replication. Adenovirus and herpesvirus simplex specifically mutated to replicate faster in cancer cells are the main replicating human pathogenic viruses used in the clinic. It is hoped that the use of selective replicating viruses that could avoid immune clearance and allow systemic administration will be available in the future for antitumoral treatment strategies. However, specific guidelines are urgently needed for clinical use of such oncolytic viruses.[53]

ULTRAVIOLET RADIATION AS A CARCINOGEN

Skin cancer offers our clearest picture of how a carcinogen causes human neoplasia. The basic principles of carcinogen exposure and slow development were discovered when Sir Percivall Pott traced scrotal cancers in adults to childhood employment as a chimney sweep[1] and they also apply to sunlight-induced cancers.[2,3] The process begins with carcinogen exposure, DNA damage, and failure to repair DNA or to apoptotically eliminate a damaged cell.[4–7] A mutant gene arises in a single cell which then expands into a mutant clone.[8] Rare cells of the clone repeat this carcinogenesis cycle to generate mutations in additional genes. Sunlight acts at each of these steps.

Epidemiologic Observations

The lifetime expectation of skin cancer in Australia is ~60 percent.[9] In the southern United States and Hawaii, non-melanoma skin cancers exceed all other cancers combined.[10–12] Basal and squamous cell carcinomas (BCCs and SCCs), and an SCC precursor, actinic keratosis (AK), are most frequent on sun-exposed skin, in outdoor workers, and at lower latitudes.[13–16] SCCs increase more quickly with dose or nearness to the equator than BCCs, and occur later in life, implying that SCC requires more sun-related steps.[16–20] In contrast, one-third of BCCs occur on body sites having only intermittent sun exposure, such as the trunk and legs.[16,21]

Melanoma also depends on sunlight. The relation to latitude is clear,[22–25] yet it is often stated that the predilection for the back and lower legs makes the relation to sunlight uncertain. This predilection reflects the large surface area of back and legs. When expressed as lesions per unit area, melanomas are 10- to 20-fold more frequent on the face and male ears than on intermittently exposed sites such as the lower legs in women, shoulders, back, or neck.[25,26] Melanomas are rare on the buttocks and soles. Melanoma appears to have two distinct origins:

1. A chronic sun damage (CSD) etiology affects the head and neck and is associated with chronic elastosis—a classic indicator of CSD—as well gene amplification of the cell cycle genes ' (/ and ' ' 2 (.[27] The slow-growing lentigo maligna melanoma and its precursor, lentigo maligna occur on habitually exposed body sites of light-skinned individuals.[28]
2. A non-CSD route involves intermittent sun exposure of sites such as the trunk. Non-CSD melanomas carry mutations in the &6% or 2 6%7 oncogene—upstream regulators of cell cycle genes—and the patients have variant alleles of the melanocortin 1 receptor.[27,29,30] Intermittently exposed body sites are the location of the melanoma increase in recent decades, melanomas in patients younger than age 50 years, and the additional melanomas seen near the equator.[23,25,31] Recreational sunburn may explain these and the twofold higher melanoma incidence in office workers compared to outdoor workers.[32,33]

Sunlight is also implicated by the susceptible population: both classes of skin cancer are more frequent in light-skinned individuals with blonde or red hair who burn rather than tan.[13,34] Compared to black-skinned individuals, non-melanoma skin cancer risk rises ~10-fold in Asians and ~100-fold in Caucasians, with a further 2- to 12-fold risk for blonde or, especially, red hair.[13,34–37] The divergence is less for melanoma, about 1:1:15.[38] In black skin, BCC is rare even in patients with the hereditary nevoid BCC syndrome (NBCCS or Gorlin syndrome).[39] Skin tumors in black patients are often scar-related, but these may be associated with sunlight as well.[36] Melanin-related effects result from less melanin in light skin,[40] less shielding by pheomelanin than eumelanin, and greater production of photosensitized reactive oxygen from pheomelanin.[41–43]

Molecular epidemiology has provided the most direct evidence for ultraviolet radiation (UVR) as the active component of sunlight: UVB signature mutations are present in human BCC, SCC, and AK (see Ultraviolet Radiation Signature Mutations). Mutant cells are associated with elastotic dermis, indicating chronic sun exposure.[44] UVB's effectiveness is due to its ability to partially penetrate the ozone layer and stratum corneum and then be absorbed by DNA.[45] The ozone layer absorbs all but 1 part per million of UVC (used in germicidal bulbs), which otherwise would be lethal; UVA penetrates well but is poorly absorbed by DNA.[45,46] Nevertheless, chronic UVA can induce tumors in mice[47] and malignantly transforms predisposed human cells.[48] The cumulative dose of sunlight required to cause BCC or SCC in adults is fairly large, approximately 10,000 and 70,000 hours of exposure, respectively.[16] Psoriasis patients receiving < 100 UVB treatments [and who had low psoralen and UVA light (PUVA) exposure] had a risk of SCC or BCC on sun-shielded sites slightly above background, and risk was threefold higher with > 300 UVB treatments.[49]

ULTRAVIOLET RADIATION CARCINOGENESIS AT A GLANCE

- Ultraviolet radiation (UVR) from the sun is the most prevalent carcinogen in humans, particularly among Caucasians.
- Annual increases continue in the incidence of all types of skin cancer.
- The importance of exposure timing, dose rate, and total UVR exposure differ between the types of skin cancer.
- Sunlight leaves characteristic mutations that identify key molecular and cellular steps in skin tumor development.
- DNA repair, apoptosis, and cell signaling pathways are critical to preventing skin cancer, and UVR affects each of these processes.
- Genetic polymorphisms in genes for DNA repair, melanin, and free radical scavenging affect skin cancer risk.
- Novel, pathway-based approaches to prevent or treat skin cancer are being developed.
- Educational and behavioral approaches are key to minimizing skin cancer rates in the future.

Some melanomas appear to be independent of sunlight: tumors of the mucosa, palms, soles, and nail beds are equally frequent in whites and blacks, have remained constant while melanomas of the skin have become epidemic, and are not associated with precursor nevi.[50] Ocular melanomas are more frequent in whites than blacks, but do not depend on latitude and have not increased in the last few decades.[51]

The Skin Cancer Epidemic

The incidence of melanoma and non-melanoma skin cancers has doubled each decade since the 1930s.[10,23,25] AK, lentigo maligna, and lentigo maligna melanoma—typically lesions of the middle-aged and elderly—are now seen in young adults. But because cancer requires several events, it is not guaranteed that this increase in skin cancer is caused by an increase in one of the sun-related events. The best evidence for sun exposure is that increases have been greatest for intermittently sun-exposed sites, such as the trunk and limbs, with little change in melanomas of the head and neck.[23,25] Increased recreational exposure is usually blamed. Another suspect has been ozone depletion; because of a steep absorption curve in the UVB region, small changes in ozone concentration greatly affect UVB penetration. (UVC is fortunately still blocked). The Antarctic ozone hole caused a 50 percent ozone reduction over southern Chile and Argentina in the last two decades, with UVB increasing up to 40-fold. Yet skin cancers in these areas are increasing at the same rate as elsewhere.[52,53] The Arctic ozone hole has been offset by screening from air pollutants, yet skin cancers in Scandinavia are rising.[54]

An iatrogenic source of increased skin cancer incidence is PUVA therapy for psoriasis, which increases the risk of SCC eightfold; in some but not all patient cohorts it raises melanoma > 14-fold[55] (see Chap. 239). BCC is not affected. Cancer is now increasing as a result of tanning beds. Individuals whose first sunbed exposure occurred as a young adult, or who had long durations or high frequencies of tanning bed exposure, already have a 70 percent higher risk of melanoma.[56]

CHARACTERISTICS OF ULTRAVIOLET RADIATION–INDUCED CANCERS AND PRECANCERS

In the United States, ~1,000,000 BCCs are diagnosed annually, as well as 100,000 SCCs and 60,000 melanomas.[11,12] Survival differs strikingly. Fewer than 1 in 10,000 BCCs will metastasize and threaten the patient (see Chap. 115). This number increases to 1 in 40 for SCC, with clinical experience indicating that SCCs on sun-exposed skin are less likely to metastasize than those arising in scars.[57] One in seven invasive melanomas is lethal (see Chap. 124). Merkel cell carcinoma (see Chap. 120) is a sun-induced cutaneous neuroendocrine cancer that will kill one in three patients diagnosed with it. Its incidence has tripled in the past 15 years to approximately 1000 per year in the United States.[57a]

The type of exposure preferentially leading to each malignancy differs. Cumulative lifetime sun exposure is strongly associated with SCC incidence.[16,20] BCC and AK instead seem to depend on reaching a certain threshold of UV exposure, often attained in youth, such that sensitive individuals develop BCC at a relatively early age, and the incidence does not increase with further exposure.[16,20,58] Case-control studies link melanoma with intense exposure early in life, with one or two blistering sunburns doubling the melanoma risk (see Chap. 124 and ref. 59). This effect may be an underestimate if, as mentioned in Epidemiologic Observations, melanoma has two origins, one depending on CSD and one on intermittent exposure and sunburns.

Children are particularly sensitive to sunlight: moving from England to Australia before age 20 years confers the higher Australian incidence of AK, SCC, BCC, and melanoma, but the risk is much less when adults immigrate.[60,61] This is not simply due to children spending more time outdoors, as < 25 percent of lifetime exposure occurs before age 18 years.[62] One explanation may be that mutant cells created in youth have more years in which to acquire the additional genetic requirements for cancer.

Precursor lesions for SCC (AK) and melanoma (nevi) are also usually related to sun exposure.[14,15,63–65] Accounting for roughly 3 million physician visits each year in the United States, AKs (see Chap. 113) are the fourth leading cause for a visit to a dermatologist.[66] They typically manifest as 1- to 3-mm scaly papules that involve erythema but often are easier felt than seen. They proceed to SCC in ~1 percent of cases if left untreated.[67] Actinic cheilitis is an analogous precancerous state on the sun-exposed lip. The importance of ongoing sun exposure is made apparent by clinical studies indicating that reducing sun exposure can reduce the number of AKs over a span of months. In randomized sunscreen studies, statistically significant decreases in AKs were seen in the sunscreen group over brief periods.[68,69] Common nevi and especially clinically atypical nevi can be precursors of malignant melanoma, with abundant nevi conferring a 10-fold risk for cancer.[22,70] Acquired melanocytic nevi begin to appear at age 1 to 5 years in proportion to sunlight exposure and are most frequent in individuals with freckles and red hair.[63,64,71] Acquired nevi carry the &6% mutations seen in non-CSD melanomas, but congential nevi instead have 26% mutations.[72]

ULTRAVIOLET RADIATION–INDUCED GENETIC ALTERATIONS

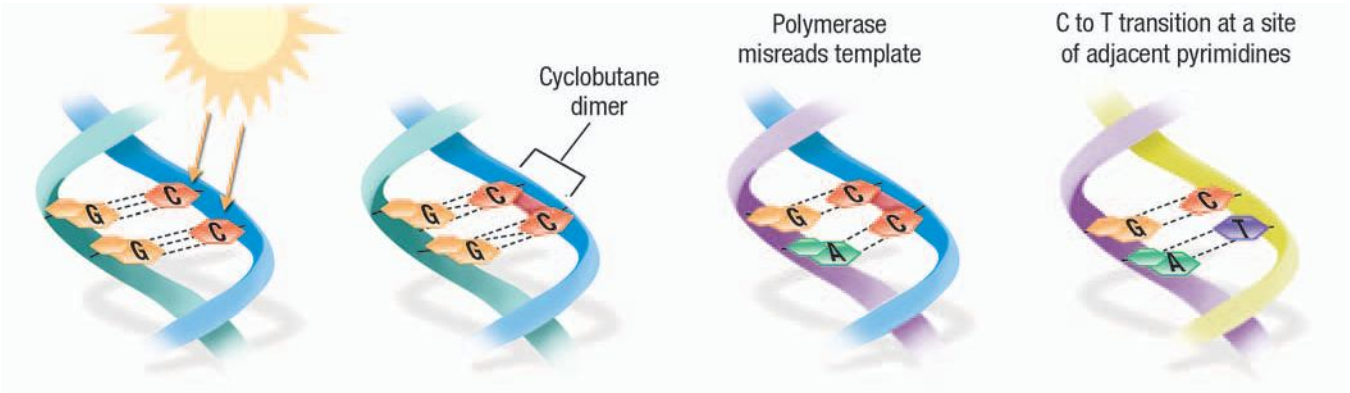
Ultraviolet Radiation–Induced DNA Damage and Repair

(2%4, 383463(9' 87 The first molecular step in sunlight-induced carcinogenesis occurs when UVB photons induce DNA photoproducts. UVB and UVC tend to be absorbed at the 5-6 double bond of pyrimidines (thymine and cytosine), allowing the bond to open.[73] If two adjacent pyrimidines are activated, their open bonds cross-react. Creating two single bonds (5-5 and 6-6) results in a cyclobutane pyrimidine dimer (Fig. 112-1). The most frequent is TT, but TC and CC cyclobutane dimers are also made. A single bond between the 6 position of one pyrimidine and the exocyclic group of the other instead creates a pyrimidine-pyrimidone (6-4) photoproduct.[74] Both photoproducts distort the DNA helix and are recognized by DNA repair enzymes.

UVA is 20-fold more frequent in sunlight but requires 1000-fold greater doses for its biologic effects.[45–47,75,76] UVA induces T-containing cyclobutane dimers and lesser numbers of oxidized purines and pyrimidines and single-strand breaks.[77] UVA generates these lesions indirectly by photosensitization (see Chap. 88). UVA also efficiently photoisomerizes UVB-induced (6-4) photoproducts to their poorly repaired and highly mutagenic Dewar isomers.[77]

Ultraviolet Radiation Signature Mutations

UVR leaves a characteristic signature when it interacts with DNA, and this



▲ *-+96) Ultraviolet radiation (UVR)–induced C to T "signature mutation." UVR causes adjacent pyrimidines on the same strand to form a cyclobutane dimer. If not repaired, the C in the dimer can be misread by the DNA polymerase or can degrade to uracil such that it erroneously pairs with adenine. The net change is that a cytosine in the sequence is converted to thymine. If both cytosines mutate, the result is CC to TT. (Modified from a Scientific American article by Brash & Leffell, 1996.)

signature remains in the tumor decades later. It has been used to answer many questions about the origin of cancer. A cyclobutane dimer or (6-4) photoproduct can lead to a mutation in two ways (see Fig. 112-1). When the lesion is copied during DNA replication, the DNA polymerase may read a damaged cytosine as a thymine and insert an adenine opposite it. At the next round of replication, the polymerase correctly inserts thymine across from adenine, with the result being a C→T substitution. Although the TT cyclobutane pyrimidine dimer is the best known and most frequent photoproduct, the thymines are not mutagenic because the <4: gene encodes a specialized polymerase (Pol eta) that adds adenines across from a T-containing cyclobutane dimer.[83] Alternatively, a mutation can arise because cyclobutane dimers accelerate deamination of their cytosines to uracil (or 5-methylcytosine to thymine), leading to a C→T substitution; no polymerase error is involved.[84] In either case, C→T mutations occur only where a cytosine lies next to a thymine or another cytosine, because the major UV photoproducts join adjacent pyrimidines. If two adjacent cytosines mutate, the result is CC→TT. This distinctive pattern of mutation, C→T where the C lies next to another pyrimidine, including CC→TT, is unique to UVR and is called the 9: WKHUHXV[85]

UV signature mutations provide a tool for deducing backward from mutations found in tumors to the original carcinogen. Nearly all experimentally created UVB or UVC mutations are located at adjacent pyrimidines, and about two-thirds are signature mutations.[85] The remaining third, typically C→A and T→C substitutions or one to two base insertions or deletions, are still caused by UV but probably arise by photosensitized production of reactive oxygen. Because this oxidative class is caused by many carcinogens, these mutations cannot identify whether their source was UVB, UVA, tobacco smoke, or intracellular oxidative phosphorylation. A set of tumors carrying the classic UV signature mutations must, however, also have some tumors with these UV-induced oxidative mutations. UVA, in contrast, only weakly induces UVB signature mutations by photosensitization but also generates oxidation-like mutations and T→G changes. The latter are rare with UVB or other carcinogens and have been proposed to be a UVA fingerprint.[86]

p53 UV signature mutations identified T as critical for preventing SCC and BCC but not melanoma.[85,87] The p53 protein is a transcription factor that controls genes involved in the cell cycle, apoptosis, and DNA repair; it also acts directly on apoptosis proteins.[7] The T gene is mutated in about one-half of all human cancers and is termed a XYQSV WTTVVWSV KIRI because cancer arises from losing its normal function rather than gaining an abnormal function as oncogenes do. Over 90 percent of SCC in U.S. patients contain these mutations, as well as three-fourths of AK. Although nearly all BCCs overexpress p53 protein, only half carry T mutations. Each mutation changes the amino acid, indicating that the mutation was selected for and contributed to tumor development, rather than being simply an indicator of sun exposure. These T mutations are most frequent at nine mutation hotspots in important functional regions of the protein. Compared to internal cancers, some skin cancer hotspots are displaced several nucleotides to lie at a site of adjacent pyrimidines.[87] Some sites may be hotspots because repair is slower there.[88] Other skin hotspots, like internal cancer hotspots, lie at 5-methylCG sites where body temperature slowly deaminates 5-methylcytosine to thymine; UVR accelerates this process.

The T mutations in AK indicate that these dysplasias are clonal; patients with multiple AKs have different mutations in each lesion.[89–91] The similarity of AK and SCC mutations supports the idea that AKs can progress to SCC. Aggressive skin tumors from patients exposed to both sun and chemicals contain multiple unrelated T mutations, as if multiple tumors arose in an abnormal field and merged.[92] XP tumors contain very frequent CC→ TT mutations, perhaps because slow repair allows more time for cytosine deamination.[93,94] Double-base mutations are also seen in conjunctival SCC, a tumor associated with human immunodeficiency virus (HIV) in sunny areas.[95] Sunscreens reduce the level of UV signature mutations.[96] In contrast, arsenic-induced BCC and SCC have non-UV T mutations; T mutations in BCCs from sun-shielded body sites resemble those seen with oxidative damage.[97,98]

Sunlight mutates T early.[89,99] Normal sun-exposed skin carries ~60,000 clones of p53-mutant keratinocytes, three to 3000 cells in size.[100] By hematoxylin and eosin staining, the cells in these mutant clones appear completely normal.[44] The early appearance of T mutations makes it possible to trace lineages in tumor development. Microdissecting lesions containing AK, carcinoma in situ, and SCC reveals that each stage contains the same T mutation.[101] Although this result shows that

each stage arose from the same founder lesion, it does not show that the stages derived from each other. To show a lineage, it is necessary to find additional mutations that appear in succession. In microdissected BCCs, one T mutation is present throughout the tumor, with various second mutations in different regions of the tumor.[102] Once both T alleles are mutated, the cell is prone to aneuploidy,[103,104] increasing the likelihood of a mutator phenotype.

,)(+) , 3+ 4%8, ; %= Nearly all sporadic BCCs have inactivating mutations in the 48' , tumor suppressor gene, a part of the hedgehog pathway (see Chap. 116); the remainder have activating mutations in its target, 71 3. The hedgehog pathway appears to be a "gatekeeper" for basal cell carcinogenesis, needing to be mutated early in BCC: minute BCCs have 48' , mutations, as do all histologic subtypes; no BCCs have loss on other chromosomes without involvement of 48' ,; and a congenital lesion that can progress to BCC, the sebaceous nevus, has 48' , allelic loss in 40 percent of cases.[105–107]

In sporadic BCCs, about three-fourths of 48' , mutations are UVR-like (either UV signature mutations or the expected UVR-induced oxidative mutations) and a further 15 percent are one or two base insertions or deletions, often adjacent to a C→ T at a dipyrimidine site.[108] BCCs from XP patients contain UVR-like 48' , and 71 3 mutations, with CC→ TT mutations overrepresented.[109,110] About 20 percent of the mutations in sporadic BCCs are not UVR-like and resemble germline mutations seen in basal cell nevus syndrome patients—deletions or insertions larger than two base pairs. This finding may relate to the clinical observation that one-third of BCCs occur on parts of the body that are not chronically sun-exposed, as well as the correlation between truncal BCC and defects in the glutathione radical-scavenging system (see Genetic Risk Factors). 48' , mutations tend to code for stop codons or frameshifts that completely inactivate the protein. In hereditary BCCs, nearly all tumors arose after losing the normal allele. This allelic loss appears related to sunlight, as NBCCS tumors are most frequent on sun-exposed skin and are rare in blacks.[39] UVB rarely causes this type of large genetic rearrangement so, in analogy to the x-ray sensitivity of NBCCS patients, UVA-photosensitized reactive oxygen may be important.

4736%0) 2 %2(9086% -30) 8 % 0+, 8 891 367 (See Chap. 239) In psoralen-treated cells, UVA forms adducts at TA, TG, or TT sequences, as well as cross-links between the two DNA strands at these sites. In human PUVA-induced keratoses, SCCs, and BCCs, about one-fourth of mutations in T or , 6%7 are psoralen-like mutations at the T of TA, TG, or TT; this proportion increases as the PUVA dose increases.[111,112] The majority of mutations, however, are UV signature mutations. The UVR-like mutations could have arisen from the UVA in PUVP, UVB treatment for psoriasis, or environmental UVB.

Melanoma Mutations (See Chap. 124)

Despite the correlation between melanoma and sunlight, genes with UV signature mutations are not prevalent. The ' (/ 2 %locus is frequently mutated or deleted in familial and sporadic melanoma (see Chap. 124). Its two distinct tumor suppressor proteins, INK4A (also known as P16) and ARF, inhibit cell cycle progression via RB and p53, respectively. INK4A inhibits CDK4/6's inactivation of the retinoblastoma protein, RB. ARF inhibits MDM2-mediated degradation of p53. Germline mutations in ' (/ 2 % are observed in ~25 percent to 40 percent of familial melanomas.[113,114] In sporadic melanoma, allelic loss of ' (/ 2 % is more common than the rare -2 / % inactivating mutations[115–117] or inactivation of -2 / %by promoter methylation.[118] The role of sunlight in these genetic events is unknown.

Oncogene mutations are found in the RAS-BRAF-MEK-ERK mitogen-activated protein kinase (MAPK) signaling pathway. This signaling cascade is normally activated on growth factor stimulation, and its sequential phosphorylation regulates cell proliferation and differentiation. Activating mutations in MAPK signaling remove the growth factor requirement. 6%7 mutations are present in 10 percent to 20 percent of melanomas and have been correlated with UVR exposure.[119–121] The most prevalent 6%* mutation in melanomas, the &6%*V600E point mutation, renders the kinase constitutively active and enhances ERK activation.[119] This mutation is present in nearly ~80 percent of acquired melanocytic nevi, suggesting a potential early role of BRAF in melanoma development.[121] The V600E mutation is not UVR-like and is associated with intermittent sunlight exposure.[27,29]

ULTRAVIOLET RADIATION–INDUCED STEPS IN CANCER AND CANCER PREVENTION

Skin tumors arise on a background of sun-damaged skin. To prevent sun damage, the skin reacts to acute and chronic UVR exposure by multiple stress responses.

DNA Damage Signaling (See Chap. 89)

A cell with damaged DNA upregulates normal p53 protein.[121a,121b] UV signaling is initiated by cyclobutane dimers and (6-4) photoproducts specifically in the small minority of actively transcribed genes, with stalled RNA polymerase both recruiting excision repair proteins and initiating signaling.[6,7] In an unknown way, this activates ATR and CHK1 kinases, which phosphorylate p53 at sites that make it resistant to proteasomal degradation mediated by HDM2. p53 then transcriptionally activates a large repertoire of genes, including the repair proteins P48, which is required for GGR and is defective in XP group E, and GADD45. Additionally, p53 functions as a chromatin accessibility factor, modifying the structure of damaged DNA and making it more accessible to repair factors. p53 also transactivates the cell cycle arrest protein P21, although in keratinocytes UVR induces P21 even without p53.[122] UVR primarily slows down S phase ("S phase delay") and induces a modest G_2 arrest, unlike ionizing radiation, which uses p53 to induce G_1 arrest. It is often said that cell cycle arrest facilitates DNA repair and survival, but there is little evidence supporting this concept; deleting the P21 cell cycle arrest protein has no effect on repair after UVR exposure.[123] These "guardian of the genome" roles of p53 are complemented by a "cellular proofreading" role in which p53 erases aberrant cells by apoptosis rather than repairing them: it transcriptionally activates the death receptor Fas and pro-apoptotic effectors Bax (Bcl-2–associated X protein), Bak, Bid, and PUMA; it directly activates Bax protein at the mitochondrion; and it inactivates E2F1, which otherwise inhibits anti-apoptotic Bcl-2.[8] This suite of UV responses is lost when p53 is mutated by sunlight. DNA damage also activates the cytoplasmically sequestered transcription factor nuclear factor κB, which then activates pro-inflammatory cytokines such as interleukin 10, growth signals, and

anti-apoptotic signals.[124,125] Finally, DNA photoproducts trigger UVR-induced systemic immunosuppression and suppression of dendritic cell antigen-presenting activity, but not inflammatory edema.[126,127]

Cytoplasmic Signaling

"The UV response" initially referred to the p53-independent activation of JNK, its target c-JUN, and, via the FOS-JUN transcription factor AP-1, induction of genes for collagenase, metallothionein, and c-JUN and c-FOS themselves.[128] The signal begins when reactive oxygen species generated by UVB or UVA photosensitization inactivate phosphatases by converting a highly sensitive cysteine residue in the catalytic site to sulfenic acid.[129,130] Dephosphorylation of growth factor receptor dimers and death receptor trimers is slowed, leading within minutes to more phosphorylated active receptors. Activated death receptors (involved in apoptosis) such as Fas and tumor necrosis factor-α (TNF-α) receptor then cluster even without a ligand, recruiting the adapter proteins DAXX and FADD and activating cytoplasmic kinases and scaffold proteins.[131–136] These activate ASK1 and MEKK 4,7 kinases and their target, JNK.[137] Phosphatase inhibition can activate JNK directly. In parallel, AP-1 also induces genes for the death receptor ligands, FasL and TNF-α.[138–140] These ligands, together with UV upregulation of FAS receptor via p53,[141] create a delayed feedback loop that, as with ionizing radiation,[142] appears to prolong the rapid but transient response triggered by UVR's inactivation of phosphatases. Without this prolongation, UVR-activated nuclear factor kappa B quickly terminates the JNK response.[143,144] This loop is important because transient JNK activation leads to cell proliferation, but constitutive JNK activation induces apoptosis.[145,146] AP-1 also induces immunomodulatory cytokines, such as interleukin 12, which facilitates NER[147]; the AP-1–induced metalloproteinases degrade dermal extracellular matrix molecules, such as collagen, and may contribute to photoaging.[148] UVR also blocks initiation of protein translation, via kinases that inactivate elongation factor eIF2α.[149]

Cellular Responses

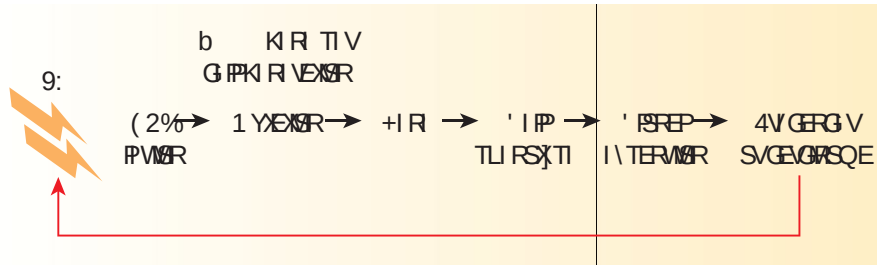
%4348 37-7 UV signaling generates sunburn cells—basal and suprabasal keratinocytes with dense, pyknotic nuclei and intensely eosinophilic cytoplasm (see Chap. 89). This apoptotic morphology is accompanied by pathognomic DNA double-strand breaks and cleaved caspase 3. UVR-induced apoptosis requires signals from both DNA damage and the cytoplasm: DNA photoproducts in active genes trigger p53 and its regulator Mdm-2,[89,150] but apoptosis also requires JNK and is partially blocked by antioxidants.[151,152] Although TNF-α is required, injecting TNF-α does not lead to sunburn cells, so UV-induced cytoplasmic signaling is not sufficient.[153,154] In fibroblasts, keratinocytes, or melanocytes with normal p53 and irradiated with physiologic UVB or UVC doses, apoptosis proceeds through the intrinsic mitochondrial pathway rather than the death-receptor/caspase 8 pathway.[152,155]

Apoptosis then prevents cancer by removing UVR-damaged cells, termed "cellular proofreading."[156] Mice accumulate mutations at a rapid rate if they are defective in apoptosis due to a defect in T or Fas ligand, or due to overexpressing the anti-apoptotic protein Survivin.[140,157,158] In Survivin's case, this increases SCC. The epidermal hyperplasia that occurs several days after UVR exposure may replace cells lost by apoptosis or may remove additional damaged or mutant cells by desquamation. The signal for hyperplasia involves both DNA photoproducts and the epidermal growth factor receptor.[159]

78) 1 ') 00 43490%8-327 In chronically UVB-exposed human skin, T -mutant clones are found at both sites of epidermal stem cells (see Chap. 44): the hair follicle, whose bulge region contributes to follicle development and transiently to wound repair, and the interfollicular epidermis, which maintains epidermal homeostasis and can also generate follicles.[100,160,161] SCCs are thought to originate in interfollicular epidermis, whereas histologic evidence and the expression pattern of PTCH indicate that BCCs originate in the follicles.[162,163] Hedgehog signaling through PTCH is crucial for maintaining skin stem cell populations and for regulating hair follicle and sebaceous gland development.[164] Chronically UV-irradiated human or mouse skin contains scattered basal cells with unusually high levels of DNA photoproducts.[165] The tumor promoter TPA (12- 3-tetradecanoylphorbol 13-acetate), which induces skin stem cells to proliferate,[166] causes these cells to disappear and be replaced by clusters of T -mutant keratinocytes. This behavior resembles that of stem cells that are quiescent and poorly repaired, at least on the parental DNA strand, until triggered to divide.[167] The immortalization-promoting enzyme telomerase is normally present only in the epidermal basal layer but is elevated in sun-exposed skin, skin precancers, and cancers.[168,169]

' 032%0) <4%27-32 3* 1 98%28 ') 007 A single mutant cell must clonally expand to reach a clinical size. Less obviously, clonal expansion facilitates the multiple genetic hit mechanism of cancer. Physiologic UVR doses create mutations at a frequency of ~10^{-4}/gene per cell division[170] (Fig. 112-2). The specific mutations needed to activate an oncogene would be rarer. Spontaneous mutations, which reflect errors by the replication machinery or DNA damage due to body temperature, are also rare, on the order of 10^{-5}.[170] The probability of mutating five genes, such as an oncogene and both alleles of two particular tumor suppressor genes, is then at best 10^{-20}. With 10^6 proliferating keratinocytes per cm^2 in human skin,[171] and ~1 m^2 exposed, fewer than 1 person in 10^{10} would have a tumor. Accounting for the 60 percent lifetime expectation of skin cancer in Australia solely in terms of genetic hits in one cell is impossible. In contrast, clonal expansion increases by 1000-fold the number of targets for the next mutation.

A stem cell's clonal expansion is normally limited to its stem cell compartment.[172] Sunlight is a key driver of clonal expansion beyond this point. The T -mutant clones in human skin are larger in chronically sun-exposed skin.[100] In mice, clones stop growing and regress when UVB treatment ends, indicating that clone expansion is due to a UVR-induced physiologic event rather than an irreversible mutation.[172,173] One of these physiologic events is UVR-induced apoptosis.[158] Once a T mutation arises, the cellular proofreading mechanism backfires: subsequent UVR exposures eliminate damaged normal cells but spare apoptosis-resistant mutants. A mutant normally restrained within its stem cell compartment then escapes to colonize the newly vacated compartment. Repeating this process results in quantized clonal expansion. Apoptosis retards or accelerates skin cancer depending on the stage: it prevents new T mutations, accelerates the expansion of T -mutant clones and papillo-



▲ *-+96) The carcinogenesis cycle. Ultraviolet radiation (UVR) makes chemical changes in DNA that create mutations when DNA is copied. Some mutations alter the function of the gene in which they occur and lead to a new cell phenotype. The abnormal cell expands into a clone that becomes the target of further DNA damage.

mas, and prevents the mutations that convert a papilloma to SCC.[140,158]

Cell–Cell Communication

Cell–cell interactions prevent abnormal cells from proliferating inappropriately. In human autotransplant experiments, BCCs transferred from their original site regressed—suggesting that an abnormal underlying dermis is required for the tumor to persist.[174] Dermal fibroblasts suppress transformed keratinocytes by secreting transforming growth factor-β that induces squamous differentiation.[175] Normal keratinocytes also suppress their transformed neighbors, and UVR interferes with these signals. Normal human keratinocytes eliminate adjacent transformed keratinocytes (mutated in T and , 6%7) by inducing cell cycle arrest and differentiation.[176] Physiologic doses of UVB cause apoptosis and differentiation in the normal cells, but not in the transformed keratinocytes, allowing the latter to clonally expand.[177] Other intercellular signals are mediated by integrins—membrane receptors for extracellular matrix proteins such as collagen ($\alpha_2\beta_1$ integrin), laminin ($\alpha_3\beta_1$), and fibronectin ($\alpha_5\beta_1$). In keratinocytes, integrins bound to such ligand provide a "do not differentiate" signal through MAPK pathways, suppressing keratinocyte apoptosis and allowing a stem cell pool to be maintained.[178,179] Integrin receptors are often dysregulated in tumors. UVB irradiation downregulates the β_1 integrin subunit. UVA downregulates the gap junction communication protein connexin 43, resembling the action of the tumor promoter TPA.[180,181]

Melanocyte proliferation is normally regulated by keratinocytes via cell–cell adhesion receptors such as E-cadherin, P-cadherin, and desmogleins; these receptors are lost in vertical growth phase melanomas.[182] UVR stimulates keratinocytes to secrete endothelin-1, which then downregulates melanocyte E-cadherin and upregulates their N-cadherin.[183] This E- to N-cadherin switch diverts melanocyte interactions away from keratinocytes and toward fibroblasts and melanocytes.[182] Endothelin also downregulates the α_6 integrin subunit,[184] upregulates the $\alpha_v\beta_3$ and $\alpha_2\beta_1$ integrins that anchor melanocytes to dermal collagen and are associated with vertical growth–stage melanoma, inhibits gap junction communication by phosphorylating connexin 43, and activates metalloproteinases associated with basement membrane invasion.

Immune Surveillance

In humans, the primary evidence cited for immune surveillance in preventing UVR-induced skin cancer is the 10- to 20-fold increase in AK and SCC on previously sun-exposed skin in transplant patients receiving chronic immune suppression to prevent organ rejection. In one Australian study, 27 percent of deaths in a heart transplant cohort were due to skin cancer.[185] The increase begins months to a few years after immune suppression is initiated, and both the AKs and SCCs are unusually aggressive.[186–190] Melanomas are also increased.[191] Several lines of evidence mar the interpretation as immune surveillance: Cyclophosphamide is a well-known mutagen. Cyclosporine promotes tumor growth in vitro and in immune-deficient mice in which there is no immune system to be suppressed.[192] Azathioprine is a mutagen when followed by UVA irradiation.[193] HIV patients do have a modestly increased incidence of SCC, but these tumors at sun-shielded sites are associated with human papillomavirus (HPV).[194] Skin cancers are often said to develop in patients who are immunodeficient due to leukemia or lymphoma. Most published reports lack controls or patient data, but an eightfold elevation in chronic lymphocytic leukemia seems valid.[195,196] Most of these patients had received immunosuppressive drugs, or radiation, so the mutagenicity caveat applies.

In contrast, Merkel cell carcinoma may be truly sensitive to immune function because its incidence increases 10- to 20-fold not only in solid-organ transplant recipients but also in HIV patients (~13-fold) and in chronic lymphocytic leukemia (see Chap. 120). The chance of metastasis and mortality also increases in all types of immunosuppressed patients. Regardless of why immune-suppressed patients are at increased risk of skin cancer, it is critical that they be monitored closely because, when caught early, even tumors in immunosuppressed patients are curable.

ANIMAL MODELS OF SKIN CANCER: CLINICAL IMPLICATIONS

GENETIC RISK FACTORS FOR ULTRAVIOLET RADIATION CARCINOGENESIS

Pigmentation and Initial Damage

Melanin has a large role in resistance to skin cancer. The Fitzpatrick skin phototypes (see Chap. 89) are determined not only by baseline pigmentation but also by a person's response to UVR (always burns, tans easily, or rarely burns). This simple UVR skin response scale can account for up to a 100-fold difference in susceptibility to skin cancers.[233] Similarly, the many molecular etiologies of oculocutaneous albinism, which result in a deficiency of normal melanin, markedly increase the risk of skin cancer (see Chap. 71). Increased skin cancer among albinos is mostly non-melanoma skin cancer, but melanomas seem elevated as well.[234] Another hereditary risk factor, red or blonde hair, is now understood at a molecular level as commonly caused by polymorphisms in the melanocortin 1 receptor[235] (see Chap. 70). This receptor is a G-protein coupled receptor that binds melanocyte-stimulating hormone and lies at a key point in melanogenesis. Certain mutations in this receptor render it insensitive to normal pigmentation signals, resulting in pheomelanin instead of eumelanin. This is an important distinction in terms of skin cancer prevention. Red or yellow pheomelanin is a markedly less effective free radical scavenger;

indeed, UVR-exposed pheomelanin is degraded with a net formation of superoxide.[42,236] Therefore, pheomelanin can act as a photosensitizer, even inducing apoptosis in nearby cells.[43] Decreased protection and increased damage from pheomelanin in the epidermis may partly underlie the markedly increased risk of skin cancer associated with red-haired individuals.

Reactive oxygen species are largely absorbed by radical scavengers, such as glutathione, before they cause significant membrane or DNA damage. Specific polymorphisms in the genes for glutathione 7-transferase confer a twofold risk for truncal AK, SCC, and BCC.[237] This genetic risk increases to sixfold in patients with high sun exposure and 12-fold in sun-exposed transplant patients.

DNA Repair and Apoptosis

XP (see Chap. 109) highlights the association between DNA repair capacity and skin cancer. Although defects in any of the XP genes result in some defect in NER, the severity of the XP disorder—number of skin tumors and life expectancy—correlates with DNA repair capacity.[82,238] The correlation between repair capacity and cancer incidence is also present in the general population. Patients with AK have a 30 percent to 50 percent reduced excision repair in their normal fibroblasts or lymphocytes.[239–241] Cells from BCC patients have reduced excision repair compared to cells from control individuals.[242] These data suggest that relatively subtle variability in DNA repair capacity contributes to an individual's risk of developing skin cancer.

Viral Sensitivity

In the rare inherited sensitivity to HPV infection termed I TH I VQSH] WPEWE ZI WY GBQM (see Chaps. 111 and 196), roughly one-half of patients will develop SCC. These SCCs are typically on sun-exposed body sites and occur decades earlier than in the general population.[243] HPV may be important in UV carcinogenesis in immunosuppressed transplant patients, as it is detected twice as frequently in SCCs from these patients as in immunocompetent controls.[244]

PREVENTION

The potential of education and sunscreen to control skin cancer remains largely unproven due to the long latency between sun exposure and skin cancer appearance. Adult sunscreen use can reduce AK by twofold.[68,69] Randomized studies of school children who aggressively applied sunscreen indicate that common nevi can be reduced.[245] A regimen of sun protection longer than the typical 2- to 4-year study would likely decrease nevi and subsequent melanoma risk more impressively. Encouraging data are emerging from Australia where education campaigns, covered sidewalks, and covered playgrounds at schools have led to a stabilization of the incidence of non-melanoma skin cancers.[9] Clearly, an effective campaign to reduce skin cancer needs to begin with school-age children. This is due to the combined factors that children younger than the age of 18 years spend a significant portion of their time in outdoor recreation, and sun damage sustained early in life has more time to contribute to UV carcinogenesis.

One could ask "how much sun is too much?" The answer will vary immensely depending on many factors such as pigmentation, whether sun exposure occurs in modest doses or large exposures, the immune status of the individual, and subtle differences in DNA repair capacity. Although highly controversial, there may be some benefit to sun exposure. Several studies have suggested twofold better survival after a diagnosis of invasive melanoma among patients with extensive sun exposure as compared to those with less exposure.[246] A potential explanation is greater vitamin D synthesis induced by UVR.

NOVEL THERAPEUTIC APPROACHES

Despite the use of sunscreens and public awareness of the effects of long-term exposure to UVR, the incidence of both melanoma and non-melanoma skin cancers continues to increase. This has led to investigation of novel chemopreventive agents that interfere with the development of cancer through diverse mechanisms. Perhaps the most important recent advance in this area is the use of imiquimod (see Chap. 221), an activator of the innate immune system through the TLR7 receptor. Imiquimod has recently been approved for treating AKs and superficial BCCs, and reports of imiquimod effects also exist for atypical melanocytic proliferations such as lentigo maligna.[247]

In terms of foods, tea appears to have chemopreventive activity. Orally administered green or black tea reduces UVR-induced skin cancers in mice to less than one-half of control levels.[248] Polyphenols and caffeine appear to be the major chemopreventive components. Topical application of caffeine was similarly effective in mice.[249] The protective effect of caffeine is attributed to its ability to induce apoptosis after UV irradiation.

Low-fat diets have been well studied as an approach to preventing skin cancer. Animal studies have shown that high-fat diets shorten the time between UVR exposure and tumor formation and markedly increase the number of tumors per animal.[250] In human trials of patients with non-melanoma skin cancer, restricting calories from fat reduced the appearance of AKs by two-thirds and the development of new non-melanoma skin cancers by one-half.[251]

Chronic UVB exposure induces inflammatory responses that have been linked to tumor formation. Inflammation induces cyclooxygenase enzymes and prostaglandins. Because prostaglandins promote keratinocyte proliferation and block differentiation, inhibiting prostaglandin formation is expected to be chemoprotective. Topical application of a nonsteroidal anti-inflammatory drug (Diclofenac) is effective in treating AKs, with 50 percent of target lesions resolving after Diclofenac treatment versus 20 percent in placebo.[252] Celecoxib, a systemic inhibitor of cyclooxygenase 2, inhibits the development of UVR-induced skin tumors in mice by twofold.[253,254] Given the side-effect profile of systemic cyclooxygenase 2 inhibitors, it appears unlikely that they will be developed for this indication.

An inducible repair process has been observed using DNA oligonucleotides that share sequence with the telomere.[255] In animal models and cell culture, these oligonucleotides can initiate multiple cellular responses, including melanin production and p53 activation, apparently in the absence of DNA damage. Topical application of these oligonucleotides to UV-irradiated mice diminished UVR-induced mutations and malignant lesions by fourfold.[256] If a therapeutically appropriate mechanism can be devised to activate this pathway, it may have utility in reversing DNA damage and preventing malignancies.

A recent development in the area of chemoprevention is the ability to augment normal DNA repair pathways. If one could increase DNA repair capacity, the mutations, chromosomal aberrations, and cell death known to be causal

for skin tumors should be reduced. The most direct application of this concept is the use of a viral enzyme (T4 endonuclease V) capable of recognizing cyclobutane dimers and accelerating the initial incision step of the NER pathway. This enzyme has been formulated into a liposomal preparation, allowing penetration into the relevant layers of skin. Indeed, studies in XP patients have shown efficacy in decreasing the residual DNA damage as well as the number of actinic keratoses.[257] There are thus diverse emerging approaches by which chemopreventive therapies may increasingly serve as an adjunct to classical UVR protection with sunscreens and avoidance of UVR exposure to skin.

Patient history
- history of actinic keratoses (AK), non-melanoma skin cancer (NMSC), malignant melanoma (MM)
- older patient (>60 years old)
- fair skin, light eyes, red or blonde hair
- history of significant cumulative UVR exposure
- high-risk genetic syndromes
- immunosuppression

Perform a total body skin examination (TBSE)

Isolated number or a handful of AKs

Biopsy lesions suspicious for NMSC and MM

Numerous AKs

First visit
- lesion-targeted treatment
  - -cryosurgery
  - -currettage
  - -shave excision
- counsel on
  - -skin self-examination
  - -proper sun-protective measures
  - -increased risk for NMSC and MM
- prevention
  - -daily broad spectrum sunscreen
  - -hats, glasses, long-sleeve shirts
  - -topical tretinoin
- encourage life-long follow-up
- schedule a follow-up visit in 2-3 months to re-evaluate treated AK lesions

First visit
- lesion-targeted treatment to most prominent AKs
  - -cryosurgery
  - -currettage
  - -shave excision
- counsel on
  - -skin self-examination
  - -proper sun-protective measures
  - -increased risk for NMSC and MM
  - -need for life-long follow-up
- discuss field therapy treatment
- schedule follow-up visit in 2-3 months

Second visit
- re-evaluate previously-treated AK sites and consider biopsies of recurrent or persistent lesions
- review counseling on AKs and skin cancer prevention
- lesion-targeted treatment for new AKs or previously-treated AKs with small residual

Second visit
- re-evaluate previously-treated AK sites and either retreat if necessary or biopsy to exclude squamous cell carcinoma (SCC)
- re-discuss patient's thoughts and preferences on field therapies

Regular follow-up with TBSE every 6-12 months

Patient able to understand and be compliant with topical field therapies and their side effects → **Begin full treatment with 5-FU or imiquimod**

Patient compliant and wanting topical field therapy but not willing to tolerate side effects of 5-FU or imiquimod → **Begin treatment with diclofenac gel**

- patient unable to comply with topical field therapy
- patient prefers one time office procedure
- patient with more cosmetic concerns
- cost not an issue

→ **• laser ablation • chemical peels • PDT • dermabrasion • cryopeeling**

• sun protection measures • topical tretinoin • regular follow-up and TBSE every 3-6 months

Sebaceous Carcinoma

Clinical Features

- Most common malignant tumor of sebaceous glands
- Usually arises on the eyelid (meibomian gland carcinoma) or periocular skin
- Presents as a firm, yellowish nodule or chalazion-like lesion
- Can mimic benign chalazion or blepharitis
- Often misdiagnosed initially
- Tends to spread locally and can invade orbit
- Metastasis is relatively uncommon but can occur to regional lymph nodes

Histopathology

- Lobules of atypical sebaceous cells
- Cells have foamy cytoplasm due to lipid vacuoles
- Nuclei are pleomorphic with prominent nucleoli
- Mitotic figures are common
- Surrounding basaloid cells may be present
- Pagetoid spread of atypical cells into overlying epidermis is characteristic
- Oil red O stain highlights intracytoplasmic lipid

Management

- Wide local excision with margin control
- Mohs micrographic surgery is preferred for periocular lesions
- Frozen section margin assessment
- Orbital exenteration for extensive disease
- Regional lymph node dissection if nodes are involved
- Radiotherapy as adjuvant or palliative treatment
- Chemotherapy for metastatic disease

Prognosis

- Prognosis is guarded
- Recurrence rate is high if margins are not clear
- Delay in diagnosis worsens prognosis
- Metastasis is associated with poor survival

Basal Cell Carcinoma

Clinical Features

- Most common skin cancer in humans
- Usually arises on sun-exposed areas of the face
- Presents as a pearly papule with telangiectasia
- Can also appear as a nodular, ulcerative, or morphoeic lesion
- Rarely metastasizes but can be locally destructive

Histopathology

- Nests of basaloid cells with peripheral palisading
- Cells have scant cytoplasm and hyperchromatic nuclei
- Stroma may show retraction artifact around tumor nests
- Mitotic figures are rare
- Keratinization is usually absent

Management

- Surgical excision with clear margins
- Mohs micrographic surgery for high-risk sites
- Curettage and electrodessication for small superficial lesions
- Cryotherapy for superficial lesions
- Topical imiquimod or 5-fluorouracil for superficial basal cell carcinoma
- Radiotherapy for elderly patients or inoperable cases
- Vismodegib or sonidegib for advanced or metastatic disease

Prognosis

- Prognosis is excellent for localized disease
- Recurrence is common if margins are inadequate
- Metastasis is rare but can be fatal when it occurs

Squamous Cell Carcinoma

Clinical Features

- Second most common skin cancer
- Usually arises on sun-exposed skin, lips, or mucous membranes
- Presents as a scaly, ulcerated, or nodular lesion
- Can arise from actinic keratosis or Bowen disease
- Has a higher metastatic potential than basal cell carcinoma

Histopathology

- Invasive nests of squamous cells with keratinization
- Keratin pearls are characteristic
- Cells show pleomorphism and hyperchromatic nuclei
- Mitotic figures are common
- Perineural invasion may be present

Management

- Wide local excision with margin control
- Mohs micrographic surgery for high-risk sites
- Curettage and electrodessication for small lesions
- Radiotherapy for elderly patients or inoperable cases
- Chemotherapy for metastatic disease

Prognosis

- Prognosis is good for localized disease
- Recurrence is common if margins are inadequate
- Metastasis is associated with poor survival

Keratoacanthoma

Clinical Features

- Rapidly growing, dome-shaped nodule with central keratin plug
- Usually arises on sun-exposed skin
- Can resemble squamous cell carcinoma clinically
- Tends to regress spontaneously after several months

Histopathology

- Crater-like lesion filled with keratin
- Cells have abundant eosinophilic cytoplasm
- Nuclei are pleomorphic with prominent nucleoli
- Mitotic figures are common
- Surrounding inflammatory infiltrate is present

Management

- Surgical excision with margin control
- Curettage and electrodessication for small lesions
- Cryotherapy for superficial lesions
- Radiotherapy for elderly patients or inoperable cases

Prognosis

- Prognosis is good for localized disease
- Recurrence is common if margins are inadequate
- Metastasis is rare but can be fatal when it occurs

Merkel Cell Carcinoma

Clinical Features

- Rare, aggressive neuroendocrine tumor of the skin
- Usually arises on sun-exposed skin of the face, neck, or extremities
- Presents as a rapidly growing, firm, red or purple nodule
- Can metastasize early to regional lymph nodes and distant sites
- Associated with Merkel cell polyomavirus infection

Histopathology

- Small, round blue cells with scant cytoplasm
- Nuclei are hyperchromatic with prominent nucleoli
- Mitotic figures are common
- Perivascular and perineural invasion may be present
- Immunohistochemistry positive for cytokeratin 20 and neuroendocrine markers

Management

- Wide local excision with margin control
- Mohs micrographic surgery for high-risk sites
- Regional lymph node dissection if nodes are involved
- Radiotherapy as adjuvant or palliative treatment
- Chemotherapy for metastatic disease
- Immunotherapy with checkpoint inhibitors for advanced disease

Prognosis

- Prognosis is guarded
- Recurrence rate is high if margins are not clear
- Metastasis is associated with poor survival

Dermatofibrosarcoma Protuberans

Clinical Features

- Rare, slow-growing tumor of the dermis
- Usually arises on the trunk or proximal extremities
- Presents as a firm, skin-colored or reddish nodule
- Can be locally aggressive but rarely metastasizes

Histopathology

- Spindle cells arranged in a storiform pattern
- Cells have scant cytoplasm and hyperchromatic nuclei
- Mitotic figures are rare
- Infiltrative growth into subcutaneous tissue
- Immunohistochemistry positive for CD34

Management

- Wide local excision with margin control
- Mohs micrographic surgery for high-risk sites
- Radiotherapy as adjuvant or palliative treatment
- Imatinib for advanced or metastatic disease

Prognosis

- Prognosis is good for localized disease
- Recurrence is common if margins are inadequate
- Metastasis is rare but can be fatal when it occurs

Kaposi Sarcoma

Clinical Features

- Vascular tumor associated with human herpesvirus 8 (HHV-8) infection
- Usually arises on the skin of the lower extremities, face, or oral mucosa
- Presents as a purple or red nodule or patch
- Can be aggressive in immunocompromised patients
- Four clinical types: classic, endemic, iatrogenic, and AIDS-related

Histopathology

- Spindle cells forming slit-like vascular spaces
- Cells have scant cytoplasm and hyperchromatic nuclei
- Mitotic figures are common
- Extravasated red blood cells and hemosiderin deposits
- Immunohistochemistry positive for HHV-8 latent nuclear antigen

Management

- Surgical excision with margin control
- Radiotherapy as adjuvant or palliative treatment
- Chemotherapy for advanced or metastatic disease
- Antiretroviral therapy for HIV-associated Kaposi sarcoma

Prognosis

- Prognosis is guarded
- Recurrence is common if margins are inadequate
- Metastasis is associated with poor survival

Cutaneous Lymphoma

Clinical Features

- Rare, heterogeneous group of lymphomas of the skin
- Usually arises on the trunk or proximal extremities
- Presents as a patch, plaque, or nodule
- Can be indolent or aggressive
- Two main types: mycosis fungoides and Sézary syndrome

Histopathology

- Atypical lymphocytes with cerebriform nuclei
- Cells have scant cytoplasm and hyperchromatic nuclei
- Mitotic figures are common
- Epidermotropism and Pautrier microabscesses
- Immunohistochemistry positive for CD3, CD4, and CD8

Management

- Topical corticosteroids for early-stage disease
- Phototherapy with psoralen and ultraviolet A (PUVA)
- Radiotherapy as adjuvant or palliative treatment
- Chemotherapy for advanced or metastatic disease
- Immunotherapy with checkpoint inhibitors for advanced disease

Prognosis

- Prognosis is guarded
- Recurrence is common if margins are inadequate
- Metastasis is associated with poor survival

Cutaneous Metastasis

Clinical Features

- Rare, secondary tumor of the skin
- Usually arises on the trunk or proximal extremities
- Presents as a nodule or plaque
- Can be indolent or aggressive
- Most common primary sites: lung, breast, and gastrointestinal tract

Histopathology

- Atypical cells with scant cytoplasm and hyperchromatic nuclei
- Mitotic figures are common
- Perivascular and perineural invasion may be present
- Immunohistochemistry positive for cytokeratin and primary tumor markers

Management

- Surgical excision with margin control
- Radiotherapy as adjuvant or palliative treatment
- Chemotherapy for advanced or metastatic disease
- Immunotherapy with checkpoint inhibitors for advanced disease

Prognosis

- Prognosis is guarded
- Recurrence is common if margins are inadequate
- Metastasis is associated with poor survival

Introduction

Actinic keratosis (AK) is a common skin lesion that develops on sun-exposed skin. It is a precursor to squamous cell carcinoma (SCC), a malignant tumor that can metastasize and cause death. Actinic keratosis is also known as solar keratosis or senile keratosis. Actinic keratosis is a clinical diagnosis, but histologic examination is necessary to confirm the diagnosis and to exclude SCC.

Epidemiology

Actinic keratosis is the most common premalignant skin lesion. It is estimated that 58 million people in the United States have AK. Prevalence increases with age, with 11% of people aged 40 years and older affected and 26% of people aged 60 years and older affected. Men are affected more than women, and fair-skinned individuals are affected more than dark-skinned individuals. Actinic keratosis is rare in children and young adults.

Pathophysiology

Actinic keratosis is caused by chronic exposure to ultraviolet (UV) radiation. UV radiation damages DNA in keratinocytes, leading to mutations in tumor suppressor genes and oncogenes. The most common mutation is in the p53 tumor suppressor gene. Other mutations include those in the p16 and p21 genes. These mutations result in uncontrolled cell growth and the development of AK.

Clinical Features

Actinic keratosis typically appears as a rough, scaly patch or papule on sun-exposed skin, such as the face, ears, scalp, neck, forearms, and hands. The lesions may be pink, red, brown, or skin-colored. They may be asymptomatic or may cause itching, burning, or tenderness. Actinic keratosis can progress to SCC, which may appear as a nodule or ulcer.

Diagnosis

The diagnosis of AK is usually made clinically. However, histologic examination is necessary to confirm the diagnosis and to exclude SCC. A biopsy is performed by removing a small piece of tissue from the lesion. The tissue is then examined under a microscope by a pathologist.

Treatment

Treatment of AK is aimed at preventing progression to SCC. Treatment options include cryotherapy, topical medications, photodynamic therapy, and surgical excision. Cryotherapy involves freezing the lesion with liquid nitrogen. Topical medications include 5-fluorouracil, imiquimod, and diclofenac. Photodynamic therapy involves applying a photosensitizing agent to the lesion and then exposing it to light. Surgical excision involves removing the lesion with a scalpel.

Prevention

Prevention of AK is important because it can progress to SCC. Prevention measures include avoiding sun exposure, wearing protective clothing, and using sunscreen. Sunscreen should be applied to all sun-exposed skin at least 30 minutes before going outdoors and reapplied every 2 hours. Sunscreen should have a sun protection factor (SPF) of 30 or higher.

Prognosis

The prognosis of AK is generally good. However, AK can progress to SCC, which can metastasize and cause death. The risk of progression to SCC is higher in people with multiple AKs, in people with a history of SCC, and in people who are immunosuppressed.

Introduction

Basal cell carcinoma (BCC) is the most common skin cancer in humans. It is a slow-growing, locally invasive tumor that rarely metastasizes. BCC arises from the basal cells of the epidermis or hair follicles, usually on sun-exposed areas of the head and neck. Risk factors include fair skin, cumulative sun exposure, and genetic predisposition syndromes.

Clinical Presentation

Patients typically present with a slowly enlarging, pearly papule or nodule with telangiectasia, sometimes ulcerated ("rodent ulcer"). Lesions may also appear as pigmented, scarring, or superficial patches. Most are painless and discovered incidentally.

Diagnosis

Diagnosis is made by clinical examination and confirmed by histopathology. Dermoscopy can support the diagnosis by revealing arborizing vessels, blue-gray ovoid nests, and ulceration. Biopsy is required before definitive treatment.

Treatment

Treatment options include surgical excision, Mohs micrographic surgery, curettage and electrodessication, cryotherapy, topical agents, and radiotherapy. Mohs surgery is preferred for high-risk locations (face, periorbital, perioral) and recurrent tumors because it maximizes tissue preservation while ensuring complete margin control.

Prognosis

Prognosis is excellent for most BCCs, with cure rates above 90% for primary tumors treated appropriately. Recurrence is more likely with aggressive histologic subtypes, poorly defined margins, or inadequate initial treatment.

Approach to a patient with known or suspected BCNS

Pediatric patients

- baseline MRI of brain, repeat yearly (if asymptomatic) until age 8
- baseline dermatologic exam, repeat yearly until first BCC develops, then every 6 months or more frequently as needed) throughout life
- digital panorex of jaw at age 3 or 4 years (or as soon as tolerated), then yearly until first jaw cyst develops. Repeat yearly (or more frequently as needed), until age 21
- pelvic u/s in girls at menarche (or earlier if symptomatic)
- molecular diagnosis, (if desired) for patients with family history and known mutation
- baseline scoliosis assessment at 1 year of age and then annually for progression if present
- routine developmental screening and referral for all children who do not meet developmental milestones

Adult patients

- baseline MRI of brain (if not done at age 8 or later)
- dermatologic exam at 4 months (or more frequently if new lesions present at each exam)
- digital panorex of jaw twice yearly until cyst free for two years, then yearly or less frequently (depending on patient's concern about radiation)
- prenatal or preconception counseling if desired

Histopathology. Nodular proliferation of basaloid cells with peripheral palisading and clefting from surrounding stroma.

Differential Diagnosis

Basal cell carcinoma, trichoepithelioma, desmoplastic trichoepithelioma, basaloid follicular hamartoma, metastatic carcinoma.

Epidemiology

Epidemiology. Basal cell carcinoma is the most common cancer in humans. Incidence is increasing worldwide. Risk factors include fair skin, cumulative sun exposure, and immunosuppression.

Etiology. Basal cell carcinoma is associated with ultraviolet radiation exposure, ionizing radiation, arsenic exposure, and genetic syndromes including nevoid basal cell carcinoma syndrome (Gorlin syndrome).

Clinical Findings. Basal cell carcinoma typically presents as a pearly papule or nodule with telangiectasia on sun-exposed skin of older adults. Variants include superficial, morpheaform, infiltrative, and nodular basal cell carcinoma.

Histopathology. Basal cell carcinoma consists of nests of basaloid cells with peripheral palisading and retraction artifact from surrounding fibromucinous stroma. Variants include superficial, nodular, infiltrative, morpheaform, and basosquamous carcinoma.

Treatment. Surgical excision with margin control is the standard treatment. Mohs micrographic surgery is preferred for high-risk locations and recurrent tumors.

Squamous Cell Carcinoma

Epidemiology

Epidemiology. Squamous cell carcinoma is the second most common cancer in humans. Incidence is increasing worldwide. Risk factors include cumulative sun exposure, immunosuppression, and chronic inflammation.

Etiology. Squamous cell carcinoma is associated with ultraviolet radiation exposure, human papillomavirus infection, chronic inflammation, and genetic syndromes including xeroderma pigmentosum.

Clinical Findings. Squamous cell carcinoma typically presents as an erythematous scaly papule or nodule on sun-exposed skin of older adults. Variants include keratoacanthoma, verrucous carcinoma, and adenosquamous carcinoma.

Histopathology. Squamous cell carcinoma consists of atypical squamous cells with keratinization and intercellular bridges. Variants include keratoacanthoma, verrucous carcinoma, and adenosquamous carcinoma.

Treatment. Surgical excision with margin control is the standard treatment. Mohs micrographic surgery is preferred for high-risk locations and recurrent tumors.

Merkel Cell Carcinoma

Epidemiology

Epidemiology. Merkel cell carcinoma is a rare but aggressive neuroendocrine carcinoma of the skin. Incidence is increasing worldwide. Risk factors include fair skin, cumulative sun exposure, and immunosuppression.

Etiology. Merkel cell carcinoma is associated with Merkel cell polyomavirus infection, ultraviolet radiation exposure, and immunosuppression.

Clinical Findings. Merkel cell carcinoma typically presents as a rapidly growing, firm, red or violaceous nodule on sun-exposed skin of older adults. Variants include trabecular, intermediate, and small cell Merkel cell carcinoma.

Histopathology. Merkel cell carcinoma consists of small round blue cells with scant cytoplasm and nuclear molding. Variants include trabecular, intermediate, and small cell Merkel cell carcinoma.

Treatment. Surgical excision with margin control is the standard treatment. Mohs micrographic surgery is preferred for high-risk locations and recurrent tumors.

Sebaceous Carcinoma

Epidemiology

Epidemiology. Sebaceous carcinoma is a rare but aggressive adnexal carcinoma of the skin. Incidence is increasing worldwide. Risk factors include fair skin, cumulative sun exposure, and immunosuppression.

Etiology. Sebaceous carcinoma is associated with ultraviolet radiation exposure, ionizing radiation, and genetic syndromes including Muir-Torre syndrome.

Clinical Findings. Sebaceous carcinoma typically presents as a yellowish nodule or plaque on sun-exposed skin of older adults. Variants include pagetoid, nodular, and infiltrative sebaceous carcinoma.

Histopathology. Sebaceous carcinoma consists of atypical sebaceous cells with vacuolated cytoplasm and nuclear pleomorphism. Variants include pagetoid, nodular, and infiltrative sebaceous carcinoma.

Treatment. Surgical excision with margin control is the standard treatment. Mohs micrographic surgery is preferred for high-risk locations and recurrent tumors.

Extramammary Paget Disease

Epidemiology

Epidemiology. Extramammary Paget disease is a rare but aggressive adnexal carcinoma of the skin. Incidence is increasing worldwide. Risk factors include fair skin, cumulative sun exposure, and immunosuppression.

Etiology. Extramammary Paget disease is associated with ultraviolet radiation exposure, ionizing radiation, and genetic syndromes including Muir-Torre syndrome.

Clinical Findings. Extramammary Paget disease typically presents as a yellowish nodule or plaque on sun-exposed skin of older adults. Variants include pagetoid, nodular, and infiltrative extramammary Paget disease.

Histopathology. Extramammary Paget disease consists of atypical sebaceous cells with vacuolated cytoplasm and nuclear pleomorphism. Variants include pagetoid, nodular, and infiltrative extramammary Paget disease.

Treatment. Surgical excision with margin control is the standard treatment. Mohs micrographic surgery is preferred for high-risk locations and recurrent tumors.

SECTION 22

MELANOCYTIC TUMORS

CHAPTER 122

Benign Neoplasias and Hyperplasias of Melanocytes

James M. Grichnik
Arthur R. Rhodes
Arthur J. Sober

Benign melanocytic proliferative lesions form a spectrum of disorders ranging from a massive accumulation of cells in multiple tissue elements to epidermal foci with a simple increase in epidermal melanocyte number. Here these lesions are separated into *melanocytic neoplasias* and *melanocytic hyperplasias.* The term *melanocytic neoplasia* is used to describe the presence of melanocytic cells in epidermal nests (defined as three or more melanocytic cells in direct contact (also known as *thèque*), within the dermis, or in other tissues. The melanocytic neoplasms are referred to as nevi (singular: nevus) and the melanocytic cells forming these nevi are referred to as *nevomelanocytes*. The term *melanocytic hyperplasia* is used to indicate increased melanocytes confined to the basal layer of the epidermis.

The specific molecular events causing melanocytic neoplasias and hyperplasias are still largely unknown. Given the identification of specific mutations (such as B-RAF)[1] and the clonal nature of nevi,[2–4] it is likely that these lesions are derived from a single progenitor cell and are the result of the dysregulation of specific cellular pathways. Given the presence of immature (less melanized) cells in many melanocytic neoplasias, it seems likely that specific underlying mutations disrupt normal melanocytic development and result in accumulation of the nevomelanocytic cells that do not complete typical migration and differentiation. The melanocytic hyperplasias are comprised of epidermal melanocytes at an increased concentration and thus alterations of normal melanocytic homeostatic mechanisms appear to be operative. These alterations could be due to a primary melanocytic defect (such as an ultraviolet-induced mutation) or homeostatic signaling changes in the local environment (possibly driven by mutations within the local keratinocytes, fibroblasts, or other resident cells).

Until discrete molecular markers are better defined, definitive subclassification of these melanocytic lesions is not possible. This heterogeneous group of disorders is currently loosely subcategorized based on clinical features and microscopic characteristics. The neoplasias described include congenital nevomelanocytic nevi (CNNs), nevus spilus, common acquired nevomelanocytic nevi (excluding atypical/dysplastic nevi covered in Chap. 123), blue nevi, pigmented spindle cell nevi (PSCN), Spitz nevi, and nodal nevi. Cutaneous melanoma is covered separately in Chap. 124. The benign melanocytic hyperplasias described in this chapter include lentigo simplex (including agminated lentigines) and solar lentigines.

CONGENITAL NEVOMELANOCYTIC NEVI

Epidemiology

The vast majority of CNNs noted at birth are small and singular, and no gender predilection has been demonstrated. The most reliable prevalence rate for CNN in a homogeneous ethnic group was obtained by biopsying all pigmented lesions in 841 white infants examined within 72 hours of birth: Of 21 infants with pigmented lesions, 7 babies (0.83 percent of 841) had a biopsy-confirmed nevomelanocytic nevus.[5] Many other series have yielded equivalent results. CNNs of 99 mm or more in diameter occur in only 1 of every 20,000

CONGENITAL NEVOMELANOCYTIC NEVUS AT A GLANCE

- Melanocytic neoplasm often exhibiting extensive nevomelanocytic infiltration of the dermis with potential involvement of the underlying adipose and muscular tissue.
- The lesions may be small or cover a substantial portion of the body surface. They are generally darker than the surrounding skin, have a rugated or smooth elevated surface, and may demonstrate long, darker, thicker hairs.
- Present at birth (or shortly thereafter—tardive congenital nevomelanocytic nevus).
- Large lesions have a significant risk of melanoma development. Cranial or midline lesions and large congenital nevomelanocytic nevus lesions with satellite lesions have an increased risk of leptomeningeal involvement.
- Synonyms: garment nevus, nevus pigmentosus et pilosus, giant nevus, verrucous nevus, and giant pigmented nevus.

▲ **FIGURE 122-1** Familial aggregation of small congenital nevomelanocytic nevi. Note small congenital nevus on the thigh of a 3-year-old white boy and on the back of his 5-year-old male sibling.

newborns, and CNNs with a garment distribution occur in only 1 of every 500,000 newborns.[6] Familial aggregation has been demonstrated for both large and small varieties of CNN (Fig. 122-1). Discordance for giant CNNs has been demonstrated for identical twins in at least three cases and for non-identical twins in two cases.

Etiology and Pathogenesis

CNNs represent a developmental abnormality of normal melanocytic development. This is presumably due to mutation (potentially NRAS)[7] that occurs in a progenitor cell that results in the abnormal extensive accumulation of melanocytic cells along migration pathways during normal development. The events leading to the nevomelanocyte accumulation may also have effects on the surrounding tissue (i.e., increased length/darker hair) possibly due to changes in the local cytokine environment of the nevomelanocytic cells. Clinical findings such as a congenital divided nevus of the eyelid (Fig. 122-2) can give us insight into when these events occur.[8] The eyelids form at between 5 and 6 weeks in utero, begin to fuse at about 8 to 9 weeks, and reopen during the sixth uterine month.[9] Because of the contiguous nature of this lesion on the upper and lower eyelids, it may be presumed that the nevomelanocytes migrated into this location sometime during or after eyelid fusion but before the eyelids split.

Clinical Findings (Fig. 122-3)

HISTORY Most CNNs are present at birth; however, there are also rare varieties of relatively large nevomelanocytic nevi (> 1.5 cm) that appear for the first time between 1 month and 2 years of life, according to parental observations and corroborated by photographs (tardive congenital nevi).

▲ **FIGURE 122-2** Congenital divided nevomelanocytic nevus of the eyelid. The nevus is contiguous when the eyelids are closed, suggesting that the lesion was formed in the developing fetus before the eyelids split (i.e., before 24 weeks).

As a child grows, the CNN should grow relatively proportionally[10] and continue to "mature." History of disproportionate growth, especially after 6 months, or change in a non-uniform manner is of concern for possible melanoma.

Both small and large varieties of CNNs have been associated with loss of pigmentation, halo depigmentation, and even regression.

CUTANEOUS LESIONS Although CNNs are on average larger than acquired nevi, for lesions less than 1.5 cm in diameter there is no specific size limitation that can be used to predict reliably whether a given nevus is congenital or acquired. Lesions attaining a diameter of 1.5 cm or more are likely to be congenital, atypical melanocytic nevi, or melanoma.

There is no completely satisfactory way to categorize CNNs as small or large. Definitions have been based on ease of removal and termed *small* if they can be excised and the wound defect closed primarily without significant deformity. Arbitrary size criteria have also considered small (< 1.5 cm; see eFig. 122-3.1 in on-line edition), medium (1.5 to 19.9 cm), and large (≥ 20 cm). Size, of course, is all relative to the location and the patient. *Giant* has been variously defined as a lesion as large as the patient's palm if it occurs on the head and neck (and twice that area for other anatomic sites), 30 percent of the body surface, or 900 cm^2 in adults (or smaller if it involves a major anatomic area) (see Congenital Nevomelanocytic Nevus At a Glance figure). Depending on the definition used, lesions that are regarded as small or medium in the newborn period may be designated medium or large, respectively, by late childhood or adulthood, given that CNNs appear to grow in proportion to the affected anatomic site.[10]

Pigmented lesion present at birth, macular or papular, may be extensive.
If diagnosis is not clear a small biopsy may be indicated.
Differential diagnosis includes café au lait macule (CALM), dermal melanocytosis (Mongolian spot), and epidermal nevus

↓

Cranial or midline large CNN and large CNN with satellite lesions, have an increased risk of neurocutaneous/leptomeningeal involvement.
MRI may be indicated

↓

When deciding whether lesion is to be excised or observed, one must weigh risk of melanoma, cosmetic and functional issues against anesthesia, surgical and scarring risks.

↓

Any lesion that is non-uniform in appearance on a single examination or demonstrates a non-uniform change over time must be considered for excision to rule out melanoma

▲ **FIGURE 122-3** Approach to the patient with congenital nevomelanocytic nevus (CNN). MRI = magnetic resonance imaging.

The contour of CNNs is usually smooth, regular, and sharply demarcated, and skin markings distort the skin surface at least slightly when assessed by oblique lighting. Some CNNs are relatively hairless. However, coarse, long, darkly pigmented hair may be present at birth, appear within the first year or two of life, or be delayed for several years. Lesions may have a smooth, pebbly, rugose, verrucous, cerebriform, or grossly lobular surface. CNNs with a cerebriform appearance may present as cutis verticis gyrata.

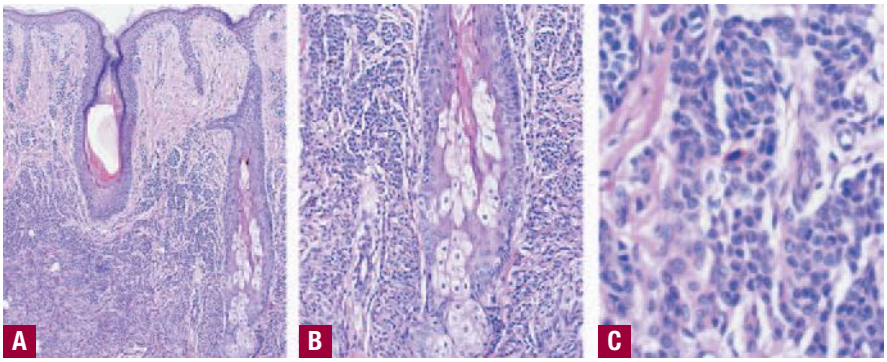
Dermoscopy may reveal a reticular pattern or globular/cobblestone pattern and may be useful in the identification of small foci of melanoma. In large congenital nevi, there can be significant variability in pigmentation and structure, and melanomas may develop in the deep components potentially reducing the utility of dermoscopy in these lesions.

Unique varieties of CNNs may have an atypical appearance and be striking for their haphazard, very dark-brown, black, or blue-black pigmentation or discontinuous pigmentation and poorly demarcated and/or irregular outlines, often associated with atypical histopathologic features. Very darkly pigmented CNNs are distinctly uncommon in whites and should suggest the possibility of atypical histopathologic features. In darkly pigmented infants, CNNs are usually darkly pigmented.

RELATED PHYSICAL FINDINGS CNNs of the head, neck, or posterior midline, and/or the presence of multiple satellite lesions associated with large CNN may be complicated by underlying cranial and/or spinal leptomeningeal melanocytosis. This phenomenon may be asymptomatic or may give rise to communicating or noncommunicating hydrocephalus, seizures, focal neurologic deficits, mental retardation, or even melanoma. CNNs need not be giant to be associated with this underlying disorder.

There is a significant association between neurofibromatosis and giant CNNs. In a study by Crowe et al.,[11] 3 of 223 patients with neurofibromatosis had extensive CNNs. In his monograph on neurofibromatosis, von Recklinghausen described 1 of 28 patients as having a giant CNN.[12] Tumors indistinguishable from neurofibroma in the absence of von Recklinghausen neurofibromatosis may develop in association with giant varieties of CNN.

Malignant degeneration of large CNNs may be associated with the relatively sudden appearance of a dermal or subcutaneous nodule, very dark pigmentation, itching, pain, bleeding, or ulceration. Often, CNN-associated melanomas appear to have evolved in nonepidermal locations.[13] Therefore, early detection of melanoma in association with a giant CNN may be difficult and not recognized until a dermal nodule or metastatic disease appears. The prognosis for patients who develop melanoma in association with giant CNNs is usually grave.[13] Unlike melanoma in general, there is no ethnic predilection for melanoma developing in giant CNN. There have been multiple cases of lethal melanoma developing in association with giant CNNs in black children.



▲ **FIGURE 122-4** Histopathologic features of congenital nevomelanocytic nevus. Nevomelanocytes in the low-magnification image (**A**) reveal dense accumulation in the lower two-thirds of the dermis; at medium magnification (**B**), these cells encroach on dermal adnexal structures (follicular and eccrine); and higher magnification (**C**) reveals dense collections of small nevomelanocytic cells.

Laboratory Tests

HISTOPATHOLOGY CNNs are characterized by the presence of nevomelanocytes in the epidermis as well-ordered thèques and/or nevomelanocytes in the dermis which are present as sheets, nests, cords, and/or single cells. Although histopathologic features are cited as being useful in distinguishing nevi as congenital or acquired, there are no known features with absolute specificity and sensitivity. The histopathologic features of very large CNNs may be divided into nevomelanocytic, neuroid, epithelioid cell and/or spindle cell, blue, and mixed types.

In the nevomelanocytic type of large CNN, the histopathologic appearance may be identical to typical acquired nevi, with nevomelanocytes in the epidermis as well-defined thèques and/or nevomelanocytes in the papillary dermis as sheets, cords, or nests. CNNs are more likely than acquired nevi to have nevomelanocytes in the lower two-thirds of the reticular dermis and to be associated with appendageal and neurovascular structures (Fig. 122-4). There may be preferential involvement of one or more epithelial structures in CNN, such as eccrine ducts, and these structures may be abundant and malformed. Veins may be preferentially involved, with an "inflammatory" appearance showing nevomelanocytes within and around blood vessel walls. Subendothelial protrusion by nevomelanocytes in lymphatic vessels may be prominent. Arrector pili may be malformed, large, and infiltrated by nevomelanocytes. Hair follicles are often quite large and frequently associated with abundant melanin in the hair bulb. Nevomelanocytes in the deep reticular dermis may be distributed as single cells or as a single-file array insinuating among collagen bundles, sheets of cells, or combinations of patterns.

Unique to the very large CNN is the occasional presence of nevomelanocytes within the substance of muscle, bone, placenta, umbilical cord, cranium, and dura mater. Very extensive CNN may be intermixed with elements of vascular malformation, hemangiomas, increased numbers of mast cells, cartilage, calcification, and even bone. There may be sparse mononuclear cell infiltrates associated with some giant CNNs. In addition to melanoma, associated tumors developing in CNN include schwannoma, neuroid tumor, lipoma, rhabdomyosarcoma, neurofibroma, sebaceous nevus, hemangioma, lymphangioma, and mastocytoma. A possible explanation for these mixed neoplasms containing melanocytic, neuronal, and other elements is that the CNN precursor cell, at least in some cases, is a pluripotent stem cell that has the capacity to give rise to multiple cell types.

In giant CNNs, nevomelanocytes have been found in regional lymph nodes

without further evidence of progressive metastatic disease. Whether this deposition occurred during the migration of the cells through the dermis or was secondary to migration from the skin after the neoplasm developed is unknown. The presence of nevomelanocytes in the nodal tissue from these lesions does not imply malignancy (see nodal nevi).

CNNs may also give rise to proliferative nodules that may be difficult to differentiate from melanoma.[14]

SPECIAL TESTS For patients with concern of possible leptomeningeal involvement, magnetic resonance imaging should be considered. For patients with concern of melanoma, positron emission tomography scan may be considered.

Differential Diagnosis (Box 122-1)

Complications

The relationship between melanoma and large CNNs is well documented. The risk of melanoma development appears to be proportional to the size of the congenital nevus. The cumulative 5-year risk has been calculated to be 2.3 percent[15] and 5.7 percent[16] in patients with congenital nevi that involve over 5 percent of the body surface. The lifetime risk of melanoma for patients with very large CNNs has been estimated to be at least 6.3 percent, based on a questionnaire follow-up study of 151 persons with CNNs examined between 1915 and 1973 in Denmark.[17] Melanoma may develop in large CNNs at any time, but the diagnosis of melanoma was established in the first 3 to 5 years of life in approximately one-half of published cases in which patients ultimately developed melanoma in association with giant CNN.

A causal association between small CNNs and melanoma is more difficult to establish than for large CNNs. When histopathologic features were studied, 6 percent to 8 percent of primary melanomas were found to be in contiguity with nevi that had microscopic features characteristic of CNN.[18,19] These findings support the concept of melanoma risk even with small congenital nevi, given the expected chance association based on body-surface-area considerations.[20]

For cranial, midline, or CNN with multiple satellite lesions, there is a risk of leptomeningeal involvement. Symptomatic leptomeningeal melanocytosis carries a poor prognosis, even in the absence of malignant degeneration.

Box 122-1

Differential Diagnosis of Congenital Nevomelanocytic Nevus

- Café-au-lait macule
- Nevus spilus
- Lentigo simplex
- Nevus of Ota/Ito
- Dermal melanocytosis (mongolian spot)
- Becker's melanosis
- Arrector pili (smooth muscle) hamartoma
- Epidermal nevus
- Nevus sebaceous
- Solitary mastocytoma

Prognosis and Clinical Course

CNNs have a dynamic evolution during body growth. CNNs at birth usually distort the skin surface at least slightly when assessed by oblique lighting and may become more elevated over time. Surface pigmentation also may change. Lightly pigmented CNNs may become more darkly pigmented, and darkly pigmented CNNs eventually may become less pigmented. CNNs also may develop a halo of depigmentation, potentially heralding spontaneous regression. Loss of pigmentation has been associated with regression of underlying nevomelanocytes and the replacement with sclerosis in some cases. Relatively hairless CNNs at birth may develop long, dark, coarse hair or may maintain a relatively normal hair density. With few exceptions, CNNs generally expand in direct proportion to growth of a given anatomic zone, although disproportionately rapid area expansion of some congenital nevi may occur during early infancy.[10] Lesions in fully grown individuals should remain stable.

Treatment

The treatment of CNNs, large and small, depends on the perceived risk of melanoma plus cosmetic and functional considerations.

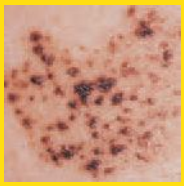
Melanoma may arise in very large CNNs even in the first several years of life. Therefore, excision of very large CNNs should be considered as early as possible, but it is probably prudent to wait until after the first 6 months of life to reduce surgical and anesthetic risks. Management of patients with very large CNNs must be individualized. Extensive involvement of the body surface, with little or no normal skin available for graft sites, may necessitate abandoning efforts at prophylactic excision and accepting lifelong surveillance to detect the earliest signs of malignant change. It may be impossible to remove every nevomelanocyte in very large CNNs, particularly when there is involvement of vital structures or deep anatomic zones. The treatment goal is to remove as much of the nevus as possible while preserving function and improving cosmetic appearance. Tissue expansion and artificial skin replacement are invaluable in repairing large wound defects. Other indications for surgical excision of very large CNNs include chronic pruritus, ulceration, and infection. Unlike surgical excision, dermabrasion and other modes of destructive therapy do not address the malignant potential of CNN; nevomelanocytes may still be left behind in the dermis, and the cosmetic results associated with destructive therapy are unpredictable. Melanoma has been reported after dermabrasion of large CNNs.[21] "Pseudomelanoma" has been described after laser treatment of a giant CNN.[22]

The approach to small CNNs needs to be considered carefully. It appears that the risk of melanoma development depends on CNN size, and therefore, smaller lesions appear to have less risk. However, due to the smaller size, complete excision of small congenital nevi may be relatively straightforward, resulting in excellent cosmetic results. Although atypical-appearing CNNs should be considered for immediate excision, careful surveillance without excision may be an option for clinically benign lesions depending on gross appearance, size, location, cosmetic and functional deficits (or improvement) resulting from excision, and general health issues. Given the risk of general anesthesia, for lesions perceived to be at low risk during the first decade of life it is appropriate to consider waiting until the child is old enough to tolerate local anesthesia. All CNNs should be documented at birth, preferably in the form of high-quality photographs that can be used to aid follow-up by parents and physicians. Follow-up is complicated by the natural evolutionary changes that take place in a nevus during body growth (i.e., surface, size, color, and hair), and periodic updates of photographs may be warranted. Suspicious changes in color, surface, or size require urgent evaluation.

Prevention

There is no known preventive approach to avoid the development of congenital nevi. Ultraviolet radiation (UVR)–induced mutations clearly play no role

NEVUS SPILUS AT A GLANCE



- Localized collection of melanocytic neoplasias forming in the background of a melanocytic hyperplasia. The neoplastic elements within the lesion tend to be histologically similar in appearance. In some lesions, the darker elements may only demonstrate increased hyperplasia compared to the background lesion.
- Clinically, the lesion appears as a hyperpigmented patch with scattered darker elements clinically similar in appearance.
- Background lesion may be present at birth but generally develops during infancy or early childhood. The neoplastic or hyperplastic elements may continue to develop within the lesion over time.
- Overall, risk is low but melanoma has been noted to develop in nevus spilus.
- Nevus spilus (derived from Greek *spilos*, meaning *spot*)—spotted nevus. Synonyms: speckled lentiginous nevus and zosteriform lentiginous nevus.
- Related variants with localized collection of nevomelanocytic neoplasias without the background of melanocytic hyperplasia are referred to as agminated nevomelanocytic nevi.
- Related variants with localized collection of melanocytic hyperplasias without the background of melanocytic hyperplasia are referred to as *agminated lentigines* (see Lentigo Simplex).

in the initial development of the lesions already present at birth. There is no current data on parental exposure that may give rise to congenital nevus formation in their offspring. The role of subsequent UVR exposure for secondary development of melanoma is unclear. However, it seems prudent to protect lesions from unnecessary UVR exposure.

NEVUS SPILUS

Epidemiology

Nevus spilus occurs in less than 0.2 percent of newborns, 1 percent to 2 percent of white school children, and 2 percent of white adults.[23] There are no prevalence data in darkly pigmented persons. There does not appear to be a gender predilection.[23] When viewed as a risk marker for melanoma, nevus spilus shows a trend for being more common in melanoma cases than in controls. Kopf et al.[23] detected nevus spilus in 5 (4.8 percent) of 105 white adults with melanoma compared with 14 (2.3 percent) of 601 dermatology outpatients.

Etiology and Pathogenesis

Nevus spilus may be postulated to develop along similar pathways as a congenital nevus, but instead of the underlying mutation creating a massive accumulation of nevomelanocytic cells in the dermis, the genetic defect creates a field of cells that are susceptible to a secondary event leading to the development of focal individual melanocytic neoplasms within the localized melanocytic hyperplasia. The specific mutations, chromosomal aberrations (mosaicism), and/or dysregulated pathways involved in this process are unknown.

Clinical Findings (Fig. 122-5)

HISTORY Rarely, nevus spilus may be present at birth. More commonly, the lesion becomes evident during infancy or early childhood. More darkly pigmented, flat, or raised elements are usually present when the lesion is first recognized, but new pigmented elements may appear over time.

CUTANEOUS LESIONS Clinically the lesion presents as a circumscribed macule/patch of tan pigmentation with features consistent with lentigo or café-au-lait macule including scattered, more darkly pigmented nevomelanocytic (or more hyperplastic) macular and/or papular elements (see figure in At a Glance box). The tan macular background pigmentation ranges from less than 1 cm to greater than 10 cm in diameter (Fig. 122-6). Although nevus spilus may occur anywhere, lesions have been noted primarily on the torso and extremities. A divided nevus spilus of the eyelid has been reported.[24] Lesions may be localized or have a segmental distribution. Giant varieties of nevus spilus may occur.

RELATED PHYSICAL FINDINGS Nevus spilus has been associated with other anomalies of vascular, central nervous system, or connective tissue origin. Multiple granular tumors and nevus flammeus have been associated with a giant nevus spilus.

Laboratory Tests

HISTOPATHOLOGY The tan background pigmentation usually consists of increased numbers of melanocytes in a lentiginous epidermal pattern. Routine and electron microscopic studies of nevus spilus may demonstrate melanin macroglobules in some cases. The flat, dark elements of nevus spilus may demonstrate foci of increased melanocytic hyperplasia or melanocytic dysplasia (architectural disorder and variable cellular atypia), whereas the raised elements usually contain collections of nevomelanocytes in the epidermis and/or dermis. The neoplastic elements of nevus spilus also may consist of epithelioid and/or spindle cell nevi, nevi with dysplastic features, or blue nevi.

SPECIAL TESTS There are no identified molecular tests of value, at least currently.

Differential Diagnosis (Box 122-2)

Complications

There are insufficient data to be certain of the natural history of nevus spilus or to comment specifically about its malignant

Background evenly hyperpigmented patch but also including scattered hyperpigmented foci. Wood's light may be required to visualize background hyperpigmention.

↓

New hyperpigmented foci may develop over time.
If one of the foci is unusual compared to the others, is non-uniform, and/or changing, it should be excised to exclude the possibility of melanoma.

▲ **FIGURE 122-5** Approach to the patient with nevus spilus.

▲ **FIGURE 122-6** Nevus spilus. **A.** Nevus spilus appearing first at age 3 years on the ankle and foot of a 25-year-old white woman. **B.** Congenital nevus spilus on the arm of a 10-year-old white male.

potential; however, caution must be exercised in affected individuals. Melanoma has been noted to develop in contiguity with nevus spilus, with some cases ending in metastatic disease and death.

Prognosis and Clinical Course

In general, nevus spilus is a benign lesion that may develop more spotted elements over time. Once developed, nevus spilus lesions are presumed to persist throughout life, although it is possible that some elements within the nevus spilus or even the entire nevus spilus itself could regress with time. There are no long-term follow-up studies of nevus spilus.

Treatment

No standard guidelines exist for the management of patients with nevus spilus. Clinical appearance (typical or atypical), history of stability or instability of pigmented elements, congenital or noncongenital onset, perceived risk of developing melanoma, and cosmetic concerns are considerations when determining whether to excise or recommend periodic clinical evaluation for life. Atypical-appearing new and/or unstable elements in nevus spilus should be evaluated by histopathologic examination to exclude melanoma. A nevus spilus with dysplastic or congenital features may have a greater risk of developing melanoma.[25,26]

Box 122-2

Differential Diagnosis of Nevus Spilus

- Agminated nevomelanocytic nevi
- Agminated lentigines
- Becker melanosis
- Congenital nevomelanocytic nevus
- Café-au-lait macule

Prevention

It is theoretically possible that increased UVR exposure results in the development of new nevomelanocytic proliferations or increased malignant potential of nevus spilus.

COMMON ACQUIRED NEVOMELANOCYTIC NEVUS

Epidemiology

Common (also called *typical*) acquired nevomelanocytic nevi develop after birth, slowly enlarge symmetrically, stabilize, and after a period of time may regress. The majority of common acquired nevi appear to develop during the second and third decades of life, although some lesions may appear in the first 6 to 12 months of life.

A number of studies have quantified the number of typical acquired nevi in different age groups. In 432 European whites between the ages of 4 days and 96 years, nevi that were 3 mm in diameter or larger were detected in females and males, respectively, at median numbers of 0 and 2 in the first decade, 10 and 16 in the second decade, 16 and 24 in the third decade, 10 and 19 in the fourth decade, 12 and 15 in the fifth decade, 4 and 12 in the sixth decade, and 2.0 and 3.5 in the seventh through the ninth decades.[27] In a series of Australian whites, the average number of nevi per person peaked at 43 for males and 27 for females during the second and third decades, respectively, and decreased to very few in the sixth and seventh decades.[28] A similar age-related prevalence rate for nevi has been documented in other countries. A difference in frequency distribution of nevi according to gender is not clear, although most series show a close to equal prevalence in males and females.

The prevalence of acquired nevi varies according to ethnicity. In African blacks, the overall prevalence of nevi (regardless

COMMON ACQUIRED NEVOMELANOCYTIC NEVUS AT A GLANCE

- A spectrum of nevomelanocytic neoplasias often subcategorized based on location of cells: cells in the epidermis (junctional), dermis (intradermal), or both areas (compound). Pathologically, the cells in the deeper dermis tend to be smaller in size and express melanocytic antigens at reduced levels.
- Clinically, the lesions tend to be uniform in appearance and relatively small in size.
- Primarily develop during childhood/young adulthood.
- Increased numbers of acquired nevi suggest an increased risk for melanoma development (see Chap. 124).
- Synonyms: nevus cell nevus, nevocellular nevus, nevocytic nevus, soft nevus, neuronevus, pigmented nevus, pigmented mole, common mole, melanocytic nevus, hairy nevus, cellular nevus, and benign melanocytoma.

of size) tends to be higher in those with lighter skin versus those with darker skin.[29] When prepubertal whites were examined for nevi, a significant association for excess nevi was documented for pale skin, blue or green eyes, blond or light-brown hair, and a tendency to sunburn, but not a tendency to freckle.[30] Other studies show variable relationships to these same parameters.

Environmental exposure to UVR appears to be a critical permissive or inciting factor for the development of nevomelanocytic nevi. In an Australian study, nevus density has been shown to increase with increasing sun intensity in the northern parts of the continent.[31] Furthermore, the use of UVR-blocking sunscreens has been shown to decrease the number of new nevi in children.[32]

Genetic factors appear to play a role in the development of nevomelanocytic nevi. The size, frequency, and distribution patterns of acquired nevi tend to aggregate in families. This observation is well documented for atypical nevi in the setting of familial cutaneous melanoma (see Chap. 124) and CNN.

Acquired nevi may be attacked by the patient's immune system, resulting in the development of a halo nevus (see History). Of 8298 whites aged 12 to 16 years, there were 51 males (1.2 percent) and 22 females (0.5 percent) who had one or more halo nevi, for an overall prevalence rate of 0.9 percent.[33] In one large series of halo nevus,[34] individuals ranged in age from 3 to 42 years (mean age, 15 years), with the vast majority of cases occurring before age 20 years.

Etiology and Pathogenesis

There has been an ongoing debate as to the origin of nevi. Although many theories have been proposed, and some supporting data are available, the critical events leading to nevus development remain a mystery. Current data suggest that nevomelanocytic nevi are clonal,[2–4] and a specific B-RAF[1] mutation has been identified and is likely to play a role in the majority of common acquired (including atypical) and congenital nevi. However, the B-RAF mutation does not seem to play a major role in blue nevi or Spitz nevi. H-RAS may play a role in some Spitz nevi, but it is clear that many more mutations are yet to be identified and correlated with the different nevus phenotypes.

Melanocytic "precursor" cells have been shown to be present in adult human skin,[39] and melanocytic stem cells have been identified in the epidermis in murine system.[40] It is assumed that these melanocytic stem cells accumulate mutations, and when needed to replenish melanocytes, they produce nevomelanocytes instead. Presumably, these nevomelanocytes then attempt to migrate along normal developmental pathways from the dermis into the epidermis. Dependent on the underlying mutation, some cells might also migrate aberrantly. The defect, timing, and local tissue influences could allow for the creation of a variety of different melanocytic neoplasias.

The clinical phenomenon of eruptive nevi also further confounds the location of the cell of origin issue. In these patients, there is the abrupt appearance of numerous similar appearing nevi often in the setting of immunosuppression or chemotherapy. Although it is generally assumed that these lesions all directly originate in the skin, drawing a comparison with epidermotropic metastatic melanoma leaves open the possibility of a circulating nevomelanocytic precursor.

Clinical Findings (Fig. 122-7)

HISTORY Acquired nevi primarily develop during childhood and early adulthood. Although nevi can clearly persist in a stable state for decades, many eventually regress. In a study following patients with dysplastic/atypical nevi, the highest rate of nevus development and nevus regression was present in patients younger than 30 years of age.[42] In later adult years, nevus counts are significantly less than those in young adulthood, and new nevi are rare, but melanoma is more prevalent. Thus, a growing lesion in an adult has a greater risk of being melanoma.

Spontaneous and concurrent development of scattered nevomelanocytic nevi often similar in appearance has been termed *eruptive nevi*. Often, these patients have experienced a blistering skin disease, immunosuppression, or chemotherapy. Eruptive nevi may have a pattern consistent with common acquired nevi, but Spitz nevi and blue nevi have also been described.

Patients may also present with the history of spontaneous development of a zone of depigmentation around a preexisting nevus. This phenomenon has been called a *halo nevus*. The halo phenomenon may be associated with acquired and CNN as well as with melanoma and non-melanocytic tumors. This phenomenon often, but not always, indicates the onset of involution and subsequent regression of the melanocytic nevus. Other names for this phenomenon include *leukoderma acquisitum centrifugum, Sutton's nevus, leukopigmentary nevus, perinevoid vitiligo,* and *perinevoid leukoderma*. Time for full evolution to depigmentation of the halo is not known, but patients report the phenomenon occurring over days to weeks, with little change occurring in the halo thereafter. The central nevus may persist or eventually disappear. Disappearance may take months to years. Areas of depigmentation that remain after the central nevus disappears may remain stationary for many years or re-pigment after months to years. There are lesions in which the nevus does not involute, and repigmentation of the depigmented halo may occur.

CUTANEOUS LESIONS Common acquired nevi vary considerably in their gross appearance. In general, appearance to the naked eye is orderly: The lesions have a homogeneous surface and coloration pattern, round or oval shape, regular outlines, and relatively sharp borders (Fig. 122-8). Common acquired nevi may be papillomatous, dome-shaped, pedunculated, or flat-topped and usually are flesh-colored, pink, or brown. More elevated acquired nevi tend to be more lightly pigmented, and flatter acquired nevi tend to be more darkly pigmented. More elevated and less pigmented lesions tend to have a prominent intradermal nevus component, whereas flatter and darker lesions have a more prominent junctional melanocytic or nevomelanocytic component and a less prominent dermal component. Very dark brown and black are unusual colors for common acquired nevi in lightly pigmented people. In contrast, dark pigmentation is usual for common acquired nevi in people who have darkly pigmented skin. Blue, gray, red, and white areas in a nevus are not typical features and ought to be viewed with suspicion. The surfaces of nevi may reveal hair that is less than, equal to, or greater than that of surrounding skin. Hair in nevi may be coarser, longer, and darker than that in surrounding skin (often these lesions reveal congenital features). Lesions on palms and soles are usually hairless. Size, shape, skin markings, and hair quality of nevi in darkly pigmented races are similar to those in whites.

Dermoscopy reveals a number of diagnostic patterns in common acquired nevi. In general, these lesions reveal a reticular or globular pattern. On the palms or soles, a parallel-furrow, lattice, or fibrillar pattern may be present. Non-

Acquired nevi are prevalent and benign. Melanoma is infrequent but deadly. One of the best tools for the differential diagnosis of an acquired lesion is dermoscopy.

↓

Dermoscopy

Step 1: establish whether a lesion is melanocytic or non-melanocytic

Classic melanocytic patterns
reticular, parallel, globular, homogenous, and starburst.

Classic non-melanocytic patterns
fingerprint, fissures, comedo-like and milia-like structures (as in seborrheic keratoses), red lacunas or sacular structures (as in hemangiomas), and spoke wheel, leaf, and ovoid structures (as in basal cell carcinaomas).

↓

Step 2: further evaluate lesions that are melanocytic or not clearly non-melanocytic for findings that may suggest melanoma. These findings may include a multi-component pattern, asymmetric dots, radial streaming, blue white veil, and irregular vascular structures. Lesions suggesting the possibility of melanoma should be excised.

↓

Dermoscopy will not be able to discriminate some of the early melanomas from acquired nevi. In order to identify these early melanomas, an additional three-step approach is recommended.

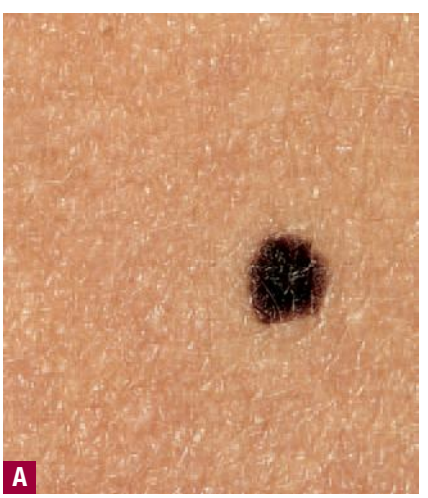
1. Is the lesion unusual? Unusual lesions would be those identified by patient as concerning, not matching the patient's average type of mole, and/or not displaying a clearly benign dermoscopic pattern.
2. Is the lesion growing? Patient history or photographic documentation may help. Baseline total skin photographs of patients at high risk for melanoma are invaluable for detecting new or changing lesions. Keep in mind that all acquired nevi are new and grow at some point, so growth alone is not a sufficient reason for excision.
3. Does the lesion have non-uniform features? As melanomas develop, they become more non-uniform. A lesion that is unusual and changing should be excised. In addition, if non-uniform features are also present, the concern for melanoma is further increased.

▲ **FIGURE 122-7** Approach to the patient with acquired nevomelanocytic nevus.

uniform patterns and parallel-ridge patterns are worrisome for melanoma.

Pigmented nevi of the nail apparatus may be a dark or light brown, extending from the nail matrix to the distal edge of the nail plate (see eFig. 122-8.1 in online edition; see Fig. 87-19 in Chap. 87); extension of the pigmentation onto the skin of the nail fold or beyond the distal nail groove should be considered suspicious for melanoma. Nevi on palms and soles, even compound nevi, may not distort the skin surface, perhaps because of a thickened stratum corneum in these sites.

The typical halo nevus has a pink or brown central nevomelanocytic nevus surrounded by a symmetric round or oval halo of depigmented skin. The central nevus may be small in typical acquired nevi, or large in acquired atypical or congenital nevi (Fig. 122-9). The halo of depigmentation is variable in size, usually a radial zone 0.5 to 5.0 cm around the central lesion. White hairs may be seen in hair-bearing depigmented areas. Alopecia areata surrounding a halo nevus has been reported. The number of halo nevi per person may be one or many, multiple lesions occurring in 25 percent to 50 percent of patients. For patients who have multiple lesions, only a few nevi are usually affected, but as many as 90 halo nevi have been reported in a single person. Any nevus in any anatomic site may be involved, but the posterior torso is involved most commonly. Lesions are usually asymptomatic. UVR may cause redness and even blistering in the perinevic halo. An atypical gross appearance of the central nevus or an asymmetric halo of depigmentation around a suspicious nevus, particularly in adults, should raise suspicion for melanocytic dysplasia or melanoma. The depigmented halo associated



◀ **FIGURE 122-8** Typical acquired nevomelanocytic nevi. **A.** Junctional nevus. A uniformly dark brown macule, round in shape, with smooth, regular border. **B.** Two compound nevi. A uniformly pigmented papule and domed nodule. The upper lesion is flatter and tan with slight central elevation. The lower lesion is older and is uniformly elevated due to an increased intradermal component.

▲ **FIGURE 122-9** Halo nevomelanocytic nevus. **A.** Acquired halo nevus on the chest of a 16-year-old white boy whose maternal grandmother had melanoma. **B.** Acquired halo nevi on the back of a 6-year-old white boy who has dysplastic nevi in the hairy scalp and a history of melanoma in his maternal grandmother. Scale in millimeters. **C.** Halo congenital nevomelanocytic nevus on the neck of a 4-year-old female of a black African-American mother and white father. This child also had scattered areas of vitiligo-like depigmentation in other sites. A 3-year follow-up after excision of the nevus revealed almost total repigmentation of the widely scattered previously depigmented areas.

with melanoma tends to be irregular and surrounds the tumor asymmetrically, and the central lesion usually has an atypical appearance.

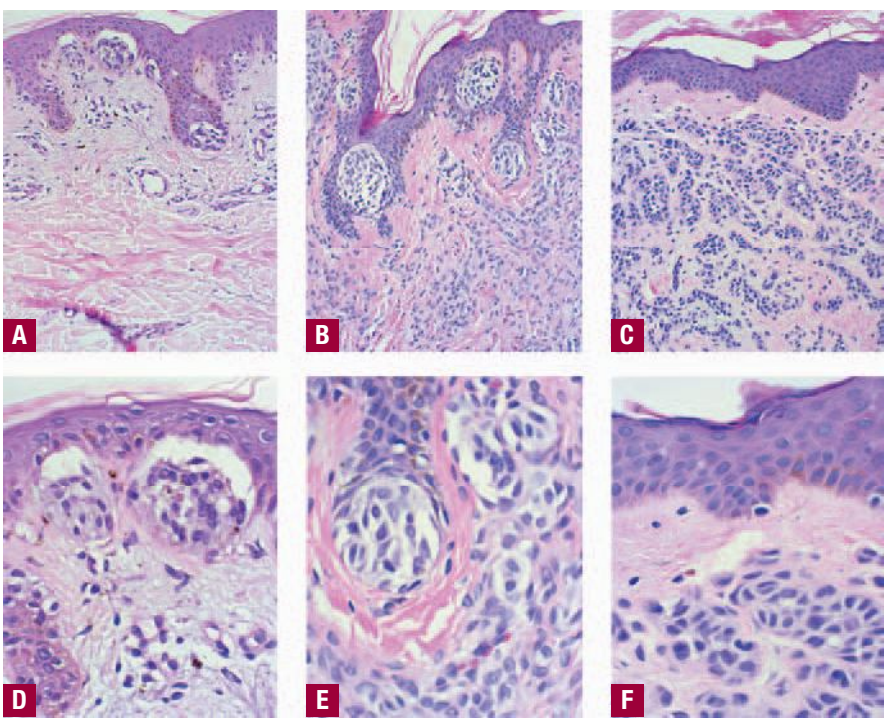
A second process that may provide some insight into factors involved in melanocytic interactions with the immune system is a process that results in the development of an eczematous dermatitis presenting as a red halo around nevi (halo dermatitis). Unlike halo nevi, regression of the nevus does not usually occur, and the eczematous changes clear over the course of several months.

RELATED PHYSICAL FINDINGS For patients with multiple nevi, there is an increased risk for cutaneous melanoma (see Chap. 124). This risk is further increased in the setting of atypical nevi and/or a personal or family history of melanoma. For patients with eruptive nevi, there may be findings suggestive of a blistering disease or immunosuppression. For patients with halo nevi, the most common associated condition is vitiligo, occurring in 18 percent to 26 percent of patients. Halo nevus may be associated with poliosis, Vogt-Koyanagi-Harada syndrome (see Chap. 72), pernicious anemia, and a personal or family history of melanoma (including ocular melanoma). Relatively large and numerous nevi are common in Turner syndrome and Noonan syndrome.

Laboratory Tests

HISTOPATHOLOGY Nevomelanocytes in the epidermis have a nuclear size similar to or larger than nuclei of epidermal melanocytes. Nevomelanocytes are arranged in nests surrounded by a smooth perimeter of epidermis and separated from nevomelanocytes by a retraction artifact (Fig. 122-10). Nevomelanocytes have abundant pale-staining eosinophilic cytoplasm and may have pseudopodic or dendritic extensions that are more evident when enzymatic or immunohistochemical techniques are used for visualization. Nuclei of nevomelanocytes are pale-staining, characterized as vacuolated or reticulated; a nucleolus is usually visible.[43] Epidermal melanocytes between junctional thèques of nevomelanocytes in typical nevomelanocytic nevi are disposed as single typical cells, with overall numbers equal to or slightly greater than that in adjacent sun-exposed skin (see Fig. 122-10).[44] The overlying epidermis is often normal in appearance but may be thickened in a lentiginous pattern (elongated and club-shaped rete ridges), with an appearance similar to seborrheic keratosis complete with horn cysts or epidermal verrucous hyperplasia similar to epidermal nevus.

The dermal component of nevi has an orderly progression from top to bottom, with larger epithelioid cells above (epi-



▲ **FIGURE 122-10** Histopathologic features of acquired nevi. Junctional nevus (**A**) and higher magnification (**D**). Compound nevus (**B**) and higher magnification (**E**). Intradermal nevus (**C**) and higher magnification (**F**). Well-formed nests of nevomelanocytes are present in the junctional and compound nevi. Sheets and cords of nevocytes are present in the dermis of the compound and intradermal nevi. A grenz zone free of nevomelanocytes is present just below the epidermis in the intradermal nevus (**C** and **F**).

dermis and superficial papillary dermis) blending into a pattern of smaller cells in the deeper dermis.

Some acquired lesions are found to have congenital features (reviewed earlier in Congenital Nevomelanocytic Nevi) suggesting that though these features may be present in congenital nevi, they are not limited to those present at birth. Others may be found to have atypical features (see Chap. 123).

Inflammatory cellular infiltrates in typical, stable acquired nevi are usually scanty[43] or absent. Melanin-laden macrophages are usually apparent in the superficial papillary dermis of nevi, their number usually proportional to degree of melanin production.[43] Blood vessel proliferation, eosinophilic fibrosis, and lamellar fibroplasia (features frequently seen in atypical melanocytic nevi) are usually not prominent in typical acquired nevi. Langerhans cell density overlying typical acquired nevi and atypical nevi is increased compared with adjacent skin.[46]

Intradermal nevi that have few or no junctional nests frequently have a grenz zone relatively free of nevomelanocytes just below the epidermis (see Fig. 122-10).

The *balloon cell nevus* is composed of peculiar foam cells comprising a portion or all of a given lesion. In addition to clear cells with single basophilic nuclei, multinucleated balloon cells and multinucleated giant cells are seen frequently. Electron microscopic studies suggest that the vacuolization of the nevomelanocytes is due to enlargement and destruction of melanosomes. There appears to be no distinguishing gross features of balloon cell nevi.

The *combined nevus* refers to the in-contiguity association of different types of melanocytic nevi. Most combined blue nevi are found in association with a benign compound nevus (acquired or congenital).

Recurrent melanocytic nevus (pseudomelanoma) is the name given to recurrent lesions after incomplete removal of a benign nevomelanocytic nevus.[47] Recurrent nevi are relatively common after superficial destructive procedures (i.e., shave biopsy or dermabrasion). A markedly atypical clinical and histopathologic appearance may accompany this recurrence, making these lesions worrisome for possible melanoma. Clinically, the recurrent nevus is confined to the scar but may be markedly irregular. Histopathologically, the recurrent lesions often demonstrate the presence of melanocytic hyperplasia in a lentiginous or junctional pattern (often to a greater extent than the original nevus). Moderate nuclear atypia may be present in 12 percent of recurrent nevi, mitotic figures in 8 percent, and pagetoid upward migration in 3 percent, raising concern about the potential biologic behavior of some recurrent lesions.[48] It is important to review the original histopathologic specimen when making re-excision and margin decisions.

No definitive pattern has been described for eruptive nevi beyond that for the nevus type.

For halo nevi, the usual histopathologic findings are a central nevomelanocytic nevus associated with a dermal band-like lymphohistiocytic infiltrate and a depigmented zone totally or almost totally devoid of epidermal melanocytes. Immunohistochemical staining [melanoma antigen recognized by T cells (Mart-1), S100 protein, or other melanocytic markers] may help to identify the residual epidermal melanocytes or the nevomelanocytes in the inflammatory infiltrate. The lymphocytes appear to be antigenically stimulated, and 80 percent are T lymphocytes, whereas B lymphocytes are scarce or absent. The T cells appear to belong to the $CD8^+$ population.[49]

The state of the nevus at the time of excision may also influence the histologic appearance. Nevi recently sunburned or traumatized may acutely have features worrisome for melanoma, and these changes resolve as the lesion heals.[52] It is also possible that nevi in their early growth phase also have more concerning features such as epithelioid cell appearance and pagetoid upward migration, but this has not yet been substantiated.

SPECIAL TESTS Special tests are not generally required. However, for patients who have eruptive nevi, given the association with immunosuppression, immunologic tests may be in order. Immunohistochemical profiles may be of value for difficult to diagnose lesions. Low Ki67 activity and loss of HMB45 in dermal (deeper) cells may help confirm a benign diagnosis. Compared to melanoma, common acquired nevi are genomically stable.[53] Gene chip analysis may be a useful way to discriminate these lesions in the future.

Differential Diagnosis (Box 122-3)

Complications

Multiple studies demonstrate that prominent numbers of nevi indicate an increased melanoma risk. Tucker et al.[54] noted a 3.4 (95 percent confidence interval: 2.0 to 5.7) adjusted relative risk for patients with 100 nevi or more (> 2 mm and < 5 mm) compared with those with fewer than 25 nevi. The relative risk was increased to 12 (95 percent confidence interval: 4.4 to 31.0) for patients with 10 or more atypical nevi compared with patients without atypical nevi. Absence of direct site specificity of nevi

  - Angioma

and melanoma suggests that nevus proneness per se indicates a general melanoma risk,[55] largely independent of hair and eye color and overall sun exposure.[56] Other traits, including skin color and freckles, may be multiplicative to the number of nevi in increasing melanoma risk.[57] The annual risk of a melanoma developing in a mole has been calculated to be approximately 1 in 200,000.[58] Furthermore, it has been reported that only 26 percent of melanomas are found in association with nevus elements.[59] Thus, it is possible that the majority of melanomas develop directly from normal skin (see Chap. 124). In patients with numerous nevi (and/or atypical nevi) these nevi are best viewed as risk markers, not precursors (or precancers) of melanoma.

Prognosis and Clinical Course

It is likely that acquired nevi evolve through a life cycle, first becoming apparent after infancy in the vast majority of cases, peaking in number during the second and third decades of life, and then disappearing by the seventh to ninth decades.[27,28,50] Regression of nevi is believed to occur by neuroid, fibrous, mucinous, or fatty degeneration.[49] Transepidermal elimination of nevomelanocytes has also been noted.[51,60] Nevi also may involute during the course of inflammatory halo depigmentation (halo nevi). The pathogenesis of the halo phenomenon is poorly understood. Available evidence suggests that both humoral and cellular factors may be responsible for nevus destruction. Atypical nevi, melanoma, and vitiligo may occur more frequently in individuals with halo nevus.

Eruptive nevi may occur as a spontaneous development of multiple nevi. These nevi are often similar in appearance to each other clinically and histopathologically. Reports generally link the initiating event to a blistering skin disease, systemic immunosuppression, chemotherapy, or treatment with "biologics."[61] The setting allowing for the eruptive nevi may also allow for melanoma development, as reported for some transplant patients, so such patients may need to be monitored carefully.

There may be relatively sudden changes in nevi that are unrelated to malignant transformation. Any single nevus that is noted to suddenly change independently should be cause for concern. Causes of sudden changes in a nevus (color, surface, or size, with or without pain, itching, ulceration, or bleeding) over days or weeks include cystic dilatation of a hair follicle, epidermal cyst formation, folliculitis, abscess formation, trauma, hemorrhage, and, in the case of a pedunculated nevus, strangulation and thrombosis. These benign causes of sudden change may require close observation for 1 to 2 weeks until resolution occurs, or excision for histopathologic examination.

The vast majority of acquired nevi are harmless. New nevi may continue to appear and disappear throughout life, but most develop during childhood and early adulthood. New or growing nevi in older individuals are more worrisome. Melanoma risk appears to be related to the number and size of nevi; patients with numerous nevi, atypical nevi, and a personal or family history of melanoma should be considered for periodic surveillance examinations for life.

Treatment

The vast majority of acquired nevomelanocytic nevi require no treatment. Indications for removal of benign-appearing lesions may include cosmetic concerns or continual irritation. Lesions with worrisome clinical features need to be excised for histopathologic examination. These features are further addressed in Chaps. 123 and 124. Dermoscopy may be used to differentiate benign and potentially malignant features. A photographic medical record can play a critical role in identifying change, or lack of change, in making risk assessments of particular nevi. All acquired nevi have an initial growth phase; other factors such as unusual features and/or non-uniformity must be considered when making a decision as to whether a particular lesion needs to be removed.[41,62]

Although a benign-appearing nevus associated with halo depigmentation need not be removed, it is reasonable to recommend periodic examination of affected individuals for atypical melanocytic nevi, vitiligo, and melanoma. Atypical-appearing central nevi, presence of an asymmetric halo, eccentric placement of a melanocytic lesion in the halo, or the setting of atypical melanocytic nevi and/or melanoma (personal or family) should suggest the need for histopathologic examination for melanoma. Cover-ups or sunscreens should be recommended for sun-exposed areas of depigmentation to prevent acute burn, chronic actinic damage, and carcinogenesis.

Complete removal of nevi is best accomplished by excision. Leaving a partially excised nevus, regardless of the initial pathology, is fraught with potentially concerning consequences of repigmentation and/or regrowth (pseudomelanoma).[47] Incisional biopsy, even for melanoma, is necessary at times, particularly for lesions that cannot be excised easily but require histopathologic diagnosis. Destructive modes of therapy (electrodesiccation, cryotherapy, dermabrasion, and laser) should be avoided and considered very carefully if used in the management of melanocytic and nevomelanocytic nevi. They have the disadvantage of not providing tissue for histopathology. Although dermabrasion has been used to eliminate pigmentation of nevomelanocytic nevi, residual nevomelanocytes in the dermis are to be expected, cosmetic outcome is often unpredictable, and recurrence with worrisome clinical features may complicate future management. Laser treatment of melanocytic and nevomelanocytic lesions has the theoretic risk of malignant transformation, but there is no proof for this.

Prevention

There appears to be a direct relationship between the number of acquired nevi and sun exposure, and a decrease with sunscreen use. Patients at increased risk should be reminded to minimize UVR overexposure. This can be done in a manner that should not impede day-to-day activities but will help reduce melanoma risk. This is best accomplished by first rearranging outdoor activities to the early morning or late afternoon/evening. This avoids the most intense UVR which hits the earth 2 hours either side of high noon. Second, cover-up clothing that blocks light transmission should be worn. Clothing is often easier to put on than sunscreen and does not rapidly wear off with sun exposure or sweating. Finally, sunscreens should be used as part of a comprehensive sun protection program.

BLUE NEVUS

Epidemiology

Blue nevi are present in fewer than 1 of 3000 newborns, in approximately 1 of 1000 aged 5 years or less, in 1 percent to 2 percent of white school children, in 3 percent of Japanese adults, and in 0.5 percent to 4.0 percent of healthy white adults. The vast majority of blue nevi are single, small, deep-blue macules or papules approximately 1 to 2 mm in diameter.

BLUE NEVUS AT A GLANCE

- Melanocytic neoplasia comprised of pigmented melanocytic cells in the mid-dermis. Includes common blue, cellular blue, combined blue, atypical, and large patch/plaque lesions.
- Lesions appear as blue, blue-gray, or blue-black papule, nodule, or plaques.
- Lesions are generally acquired but may be congenital.
- Cellular blue nevi may have an elevated risk for development of melanoma.
- Synonyms: benign mesenchymal melanoma, blue neuronevus, chromatophoroma, melanofibroma, Jadassohn-Tièche nevus, and dermal melanocytoma.
- Related lesions include nevus of Ota/Ito and mongolian spot.

Multiple blue nevi may be associated with lentigines, cardiac myxoma, and mucocutaneous myxomas [lentigines, atrial myxomas, mucocutaneous myxomas, and blue (LAMB) nevi, Carney complex]. Blue nevi have been associated with nodular mastocytosis, and a histogenic relationship has been claimed for melanocytes and mast cells.[63] Blue nevi have been reported to occur in oral mucosa, uterine cervix, vagina, spermatic cord, prostate, and lymph nodes.[64]

Etiology and Pathogenesis

The origin of common blue nevi and cellular blue nevi is unknown, but they may be derived from a mutant precursor cell resulting in the accumulation and differentiation of the melanocytic cells in the dermis instead of their normal location in the epidermis. Differentiation towards hair follicular melanocytes is possible. Some varieties of cellular blue nevi stain for CD34,[65] suggesting a potential "stem cell" origin. Bednar's tumors (dermatofibrosarcoma protuberans including cells with melanocytic marker expression) also express $CD34^+$ suggesting a similar stem cell origin for these tumors with different differentiation pathways.[66] Nevus of Ito/Ota is related to common blue nevi but represents an extensive localized acquired proliferation. The extension of these neoplasms along specific neural pathways may provide insight into the etiology of these dermal proliferations, including the possible role of certain neural factors. Although no specific mutations have been attributed to blue nevi, in the murine system a number of genes have been identified that result in the accumulation of dermal melanocytic cells,[67] and it is possible that some of these mutations may be involved in human dermal melanocytoses.

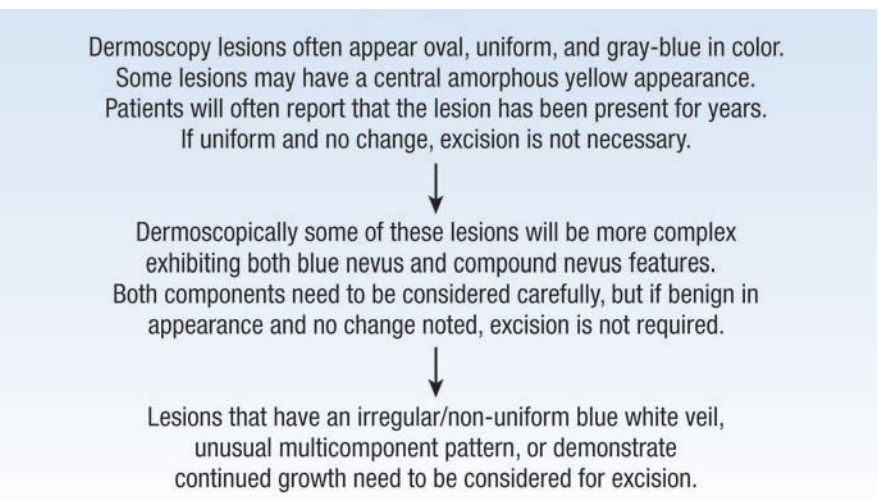
Clinical Findings (Fig. 122-11)

HISTORY Common blue nevi are usually acquired, and once developed should remain stable. Nevus of Ota and Ito may share similar underlying defects to blue nevi and are also often acquired (in early childhood, often before age 1 year or around puberty) but are far more extensive encompassing a portion of trigeminal (ophthalmic and maxillary) and brachial (posterior supraclavicular and lateral cutaneous) nerve distributions respectively. Dermal melanocytosis (mongolian spot) may also be related to blue nevi, but is usually present at birth or within the first few weeks of life and centered over the lumbosacral area. These lesions usually regress in early childhood but may persist in approximately 10 percent of cases.

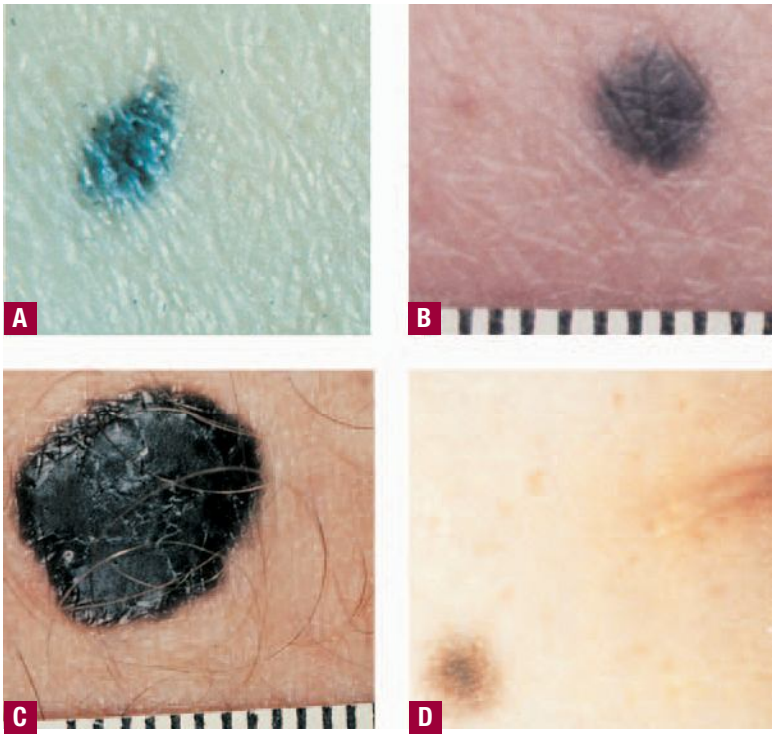
CUTANEOUS LESIONS Common blue nevi are usually solitary, asymptomatic blue, blue-gray, or blue-black papules, usually less than 10 mm in diameter (Fig. 122-12). The blue-gray color of blue nevi is an optical effect of blue light backscatter from the skin over the dermal melanin (Tyndall effect). Hypopigmented, target or targetoid, and combined blue nevi (compound nevomelanocytic nevus and a blue nevus) also exist. Common blue nevi occur anywhere, but about half the reported cases present on the dorsa of hands and feet. Usually, the common blue nevus is singular, but rarely, lesions may be multiple and agminated or arranged in large plaques consisting of multiple solitary papules or nodules with intervening areas of blue discoloration. Common blue nevi also occasionally may have satellite lesions that may be mistaken for melanoma metastasis.[68] Rare giant varieties of congenital blue nevus occur, often with multiple satellite lesions.[13] The large plaque blue nevus (pilar neurocristic hamartoma) may occasionally be associated with a background of lentigo simplex.

The deep penetrating nevus may be considered a unique form of blue nevus, but some would include this lesion in the category of Spitz nevus. Deep penetrating nevi are darkly pigmented, blue-black papules or nodules, mostly on the head and neck or upper extremities, 2 to 9 mm in diameter, and occurring predominantly in the first four decades of life, including childhood.[69]

Cellular blue nevi are blue-gray or blue-brown nodules or plaques 1 to 3 cm in diameter, occasionally larger (see Fig. 122-12C). Their surface is usually smooth but may be irregular. Approximately one-half the cases are located on the buttocks or sacrum. Cellular blue nevi may develop in association with CNN, occasionally with target appearance. Cellular blue nevus differs from the common blue nevus in that it is usually larger, more ele-



▲ **FIGURE 122-11** Approach to the patient with blue nevus.



▲ **FIGURE 122-12** Blue nevus. **A.** Common blue nevus appearing as an acquired blue-gray papule on the shoulder of an 18-year-old white woman. **B.** Common blue nevus appearing as an acquired blue-gray papule on the buttock of a 62-year-old white man. **C.** Cellular blue nevus appearing as a congenital blue papule on the low back of a 30-year-old white man. **D.** Combined common blue nevus–nevomelanocytic nevus appearing as a brown papule with a blue-gray center on the cheek of a 12-year-old white boy, beginning as a pinpoint dot at age 1 year and enlarging slowly over time. Scale in millimeters.

vated, more aggressive locally, and occasionally associated with lymph node "benign metastasis." Complicating the picture is the fact that melanoma may develop in a cellular blue nevus.

Malignant blue nevus (melanoma) may develop in contiguity with a cellular blue nevus, nevus of Ota, combined congenital blue nevus, or de novo. Malignant blue nevus presents as an expanding dermal nodule with or without ulceration. There is some dispute as to whether malignant blue nevus should be considered a separate entity from melanoma or simply referred to as a *melanoma developing in a blue nevus*.

RELATED PHYSICAL FINDINGS The presence of epithelioid blue nevi may warrant consideration of Carney complex/myxoma syndrome/LAMB syndrome, with evaluation for related findings, including atrial myxomas and endocrine tumors.

Laboratory Tests

HISTOPATHOLOGY In common blue nevi, dermal melanocytes appear as melanin-containing fibroblast-like cells grouped in irregular bundles admixed with melanin-containing macrophages, associated with excessive fibrous tissue in the middle or upper reticular dermis, occasionally extending downward to subcutaneous fat or upward to papillary dermis (Fig. 122-13). Elongated melanin-producing dermal melanocytes in common blue nevi usually lie with their long axis parallel to the epidermis. Except in the case of combined blue nevus (with a compound nevomelanocytic nevus component), the epidermis in common blue nevi appears normal. Combined blue nevi have been noted in 1 percent of melanocytic nevi excised for histopathologic examination.[70]

In cellular blue nevi, there is usually a component of a common blue nevus plus fascicles of spindle-shaped cells with ovoid nuclei and abundant pale cytoplasm with little or no melanin, and often epithelioid cells, present in the dermis and often in subcutaneous fat in nests, bundles, and neuroid forms with little or no intervening stroma (see Fig. 122-13C and D). Epithelioid cell and amelanotic varieties of the cellular blue nevus have been described. Epithelioid blue nevi have been reported in association with cardiac myxoma[73] or in isolation.[74] Histopathologic diagnosis may be difficult when the common blue nevus component and melanin production are sparse or inapparent. Differentiation of some cellular blue nevi from melanoma can be difficult. Occasionally, small groups of well-differentiated melanocytes are present in the marginal sinus or parenchyma of lymph nodes draining the anatomic site of the cellular blue nevus, making it difficult to differentiate true metastasis from pseudometastasis. It is likely that "inert" deposits of melanocytes in the capsules and peripheral sinuses of lymph nodes draining some varieties of cellular blue nevus are transported passively (see Nodal Nevi).

The malignant blue nevus is a variant of melanoma, distinguished from cellular blue nevus by invasiveness, cellular atypia, pleomorphism, atypical mitoses, and areas of necrosis.

SPECIAL TESTS Imaging tests of the heart may be required if there is concern for Carney complex/myxoma syndrome/LAMB syndrome.

Differential Diagnosis (Box 122-4)

Complications

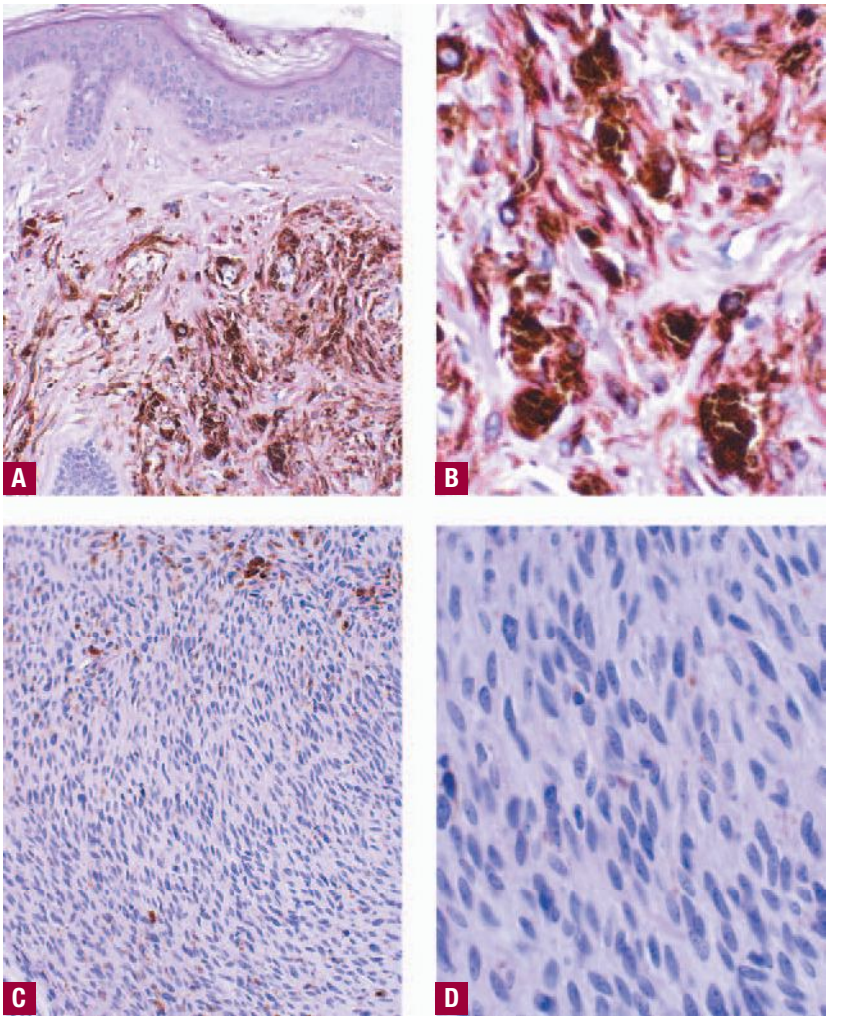
A major complication of blue nevi is the potential risk of melanoma. This risk appears to be highest for cellular blue nevi. Melanoma has been noted to evolve in large blue nevus patches or plaques and in associated with nevus of Ota and Ito.

Prognosis and Clinical Course

The natural evolution has not been studied for common blue nevi or cellular blue nevi. It is likely that once established, blue nevi remain unchanged or possibly regress over time. "Change" is worrisome for melanoma development.

Treatment

A common blue nevus that is stable for many years in an adult usually requires no therapy. Sudden appearance of a blue nodule, expansion of a pre-existing blue nodule, a congenital blue nodule, or a relatively large blue nodule or plaque greater than 10 mm in diameter should be considered for histopathologic examination. Excision should include subcutaneous fat to ensure complete removal of deep dermal melanocytes, which are frequently present in the subcutaneous tissue of cellular blue nevus. The large plaque blue nevus (pilar



▲ **FIGURE 122-13** Histopathologic features of common and cellular blue nevi. Common blue nevus (**A**) and higher magnification of the dermal component (**B**) revealing heavily pigmented, elongated melanocytes. Cellular blue nevus (**C**) and higher magnification (**D**) revealing sheets of melanocytes with ovoid nuclei.

neurocristic hamartoma) requires consideration for excision or periodic evaluation for suspicious change. Cellular blue nevus should be evaluated for excision because of its malignant potential.

Prevention

The causative factor in eruptive blue nevi has been attributed to sun exposure.[75] Thus, as with other nevi, it is reasonable to minimize excessive UVR exposure.

Box 122-4

Differential Diagnosis of Blue Nevus

- Primary or metastatic melanoma
- Glomus tumor
- Pyogenic granuloma
- Sclerosing hemangioma
- Dermatofibroma
- Ochronosis

PIGMENTED SPINDLE CELL NEVUS

Epidemiology

The mean age of presentation has been reported as 25.3 years, ranging from 2.5 to 56.0 years of age.[76] Similar age ranges have been reported in other studies.[77] The majority of cases occur in the third decade of life. Female patients outnumber male patients with reported ratios of 2:1,[76] 1.4:1.0,[77] and 1.3:1.0.[78] The majority of these lesions are found on the extremities with reported frequencies of 67.0 percent,[76] 69.6 percent,[78] and 75.0 percent.[77] There is a preference for the lower extremity, especially the thigh, with the back being the next most common site.[77]

Etiology and Pathogenesis

It may be presumed that PSCN are derived from the same progenitor cells giving rise to epidermal melanocytes and nevomelanocytes. No known specific mutation has been identified.

PIGMENTED SPINDLE CELL NEVUS AT A GLANCE

- Acquired, benign melanocytic tumors comprised of heavily pigmented spindle-shaped melanocytic cells confined primarily to the epidermis.
- The pigmented spindle cell presents as a jet black lesion often with "starburst" appearance.
- These nevi are thought to develop quickly and then stabilize.
- Malignant degeneration is thought to be rare.
- Synonyms: Reed nevus, pigmented Spitz nevus.

Clinical Findings (Fig. 122-14)

HISTORY PSCN was first described by Reed in 1975.[79] These lesions are generally detected as acquired lesions, often during the third decade of life. At presentation, patients often note that the lesion has increased in size.[77,78] It is not known how quickly these lesions grow, but growth may be relatively rapid as one case report of a lesion on a 3-year-old child documented significant growth over a 3- and 6-month period.[80] Once fully developed, it is assumed that these lesions will remain stable, but the full natural history of these lesions is not well characterized.

CUTANEOUS LESIONS The PSCN is usually a sharply circumscribed, uniformly darkly pigmented papule[76–78] (Fig. 122-15). Dermoscopically, most of the lesions are jet black but may be blue-gray or brown. In the initial growth phase, the lesions may have a globular appearance[80] but the vast majority of these lesions are uniformly dark centrally, with a sharp interface with surrounding skin often exhibiting streaks/pseudopods and giving the lesion a starburst appearance.

Dermoscopically, this lesion is often diffusely jet black with a sharp well defined border. The border should interface with the skin in a similar (uniform) manner for the full circumference of the lesion. The pattern is often "starburst" in appearance.

↓

Non-uniform edge, active growth, and/or atypical features warrant excision

▲ **FIGURE 122-14** Approach to the patient with pigmented spindle cell nevus.

RELATED PHYSICAL FINDINGS No known association.

Laboratory Tests

HISTOPATHOLOGY PSCN consists of vertically oriented fascicles of spindle-shaped, pigment-producing melanocytes (Fig. 122-16); some pagetoid upward migration may be present, but the lesion can be distinguished from melanoma by uniform nuclei, uniform cellular detail, and distinctive pattern of growth. Almost all cases of pigmented spindle cell nevus have a lymphohistiocytic host response. Spindle cells extend down eccrine ducts in 40 percent and involve hair follicles in 22 percent of lesions.[76] There is an overlap of these lesions with Spitz nevi. In a review of 91 PSCN by Sagebiel et al.,[76] cells were predominantly spindle in 74 percent and mixed spindle cell and epithelioid cell in 26 percent of patients. There are atypical variants of PSCN in which there are architectural alterations and striking cellular atypia.[78]

SPECIAL TESTS No known specific mutation or genetic markers.

Differential Diagnosis (Box 122-5)

Complications

There are no reported complications, but misinterpretation of benign or malignant behavior of the lesion could result in unnecessary or insufficient treatment, respectively.

Prognosis and Clinical Course

The PSCN are thought to be benign. No local recurrence or distant spread was noted for 38 patients followed for an average of 14 months.[76] In another study, 57 patients were followed for an average of 6 years and again no local recurrence or metastasis was noted.[77]

Treatment

If there is clinical concern, these lesions should be excised with a narrow margin of normal skin.

Box 122-5

Differential Diagnosis of Pigmented Spindle Cell Nevus

- Spitz nevus
- Blue nevi
- Hematoma
- Atypical nevomelanocyte
- Melanoma

Prevention

The role of UVR exposure in the development of PSCN is unknown. Generally, it is best to avoid UVR overexposure.

SPITZ NEVUS

Epidemiology

An annual incidence rate of 1.4 cases of Spitz nevus per 100,000 individuals has been estimated in Australia, compared with 25.4 per 100,000 individuals for cutaneous melanoma during the same time interval.[81] Among melanocytic nevi excised in children, 1 percent to 8 percent of cases are interpreted as Spitz nevus.[82] In a case series of 308 patients with Spitz nevi reported by Allen,[83] 15 percent of lesions occurred in adolescents and adults, the oldest patient being 56 years of age. There appears to be no gender predilection for Spitz nevus. Published cases have been described primarily in whites.

Etiology and Pathogenesis

It may be presumed that Spitz nevi are derived from the same progenitor cells that give rise to epidermal melanocytes and nevomelanocytes. Unlike common

SPITZ NEVUS AT A GLANCE

- Spitz nevi represent a spectrum of unique, usually acquired lesions, exhibiting epithelioid and often spindle-shaped melanocytic cells with abundant eosinophilic cytoplasm and large nuclei. Often develop in the dermis with some involvement of the overlying epidermis. Atypical variants exist.
- Clinically, the lesion is often a pink, dome-shaped papule.
- Thought to develop quickly and then stabilize. Their clinical presentation and histopathology can cause diagnostic concern for melanoma.
- Synonyms: Spitz tumor, nevus prominens et pigmentosus, pseudomelanoma, spindle and epithelioid cell nevus, nevus of large spindle and/or epithelioid cells, and compound melanocytoma. The previously used terms *Spitz's juvenile melanoma*, *benign juvenile melanoma*, and *prepubertal melanoma* should not be used.

acquired nevi and congenital nevi, the B-RAF mutation does not appear to be involved. Amplifications of chromosome 11p and H-RAS and activating mutations of H-RAS have been noted in a subset of Spitz nevi.[84] Heritable genetic factors have not been investigated systematically, but there is a single report of multiple tumors in identical twin boys.[82] The role of trauma in the histogenesis of Spitz nevi is speculative. One case has been reported at the site of bacille Calmette-Guérin vaccination.[85]

Clinical Findings (Fig. 122-17)

HISTORY The rate of growth, period of stabilization, and rate of regression of Spitz nevi are not known. The duration of solitary Spitz nevus before presentation is usually less than 9 months. Lesions usually show an increase in radial size over time, some gradual and others rapid.[86] Based on patients with eruptive Spitz nevi, regression has been reported to occur and may even occur in some lesions while new lesions are appearing.[87]

CUTANEOUS LESIONS The most common variety of Spitz nevus is solitary, asymptomatic, pink or red, hairless, firm, and dome-shaped (Fig. 122-18). Some Spitz nevi may resemble a keloid. The surface is commonly smooth, and the borders may fade into surrounding skin. Verrucous, scaly, stippled, crusted, or (rarely) eroded lesions have been noted. Spitz nevi are usually asymptomatic, but pruritus, tenderness, and/or bleeding may occur.[82] A halo of depigmentation has been associated with several cases of Spitz nevus.[33,88] Spitz nevi are part of a spectrum in which some also include PSCN and deep penetrating nevi.

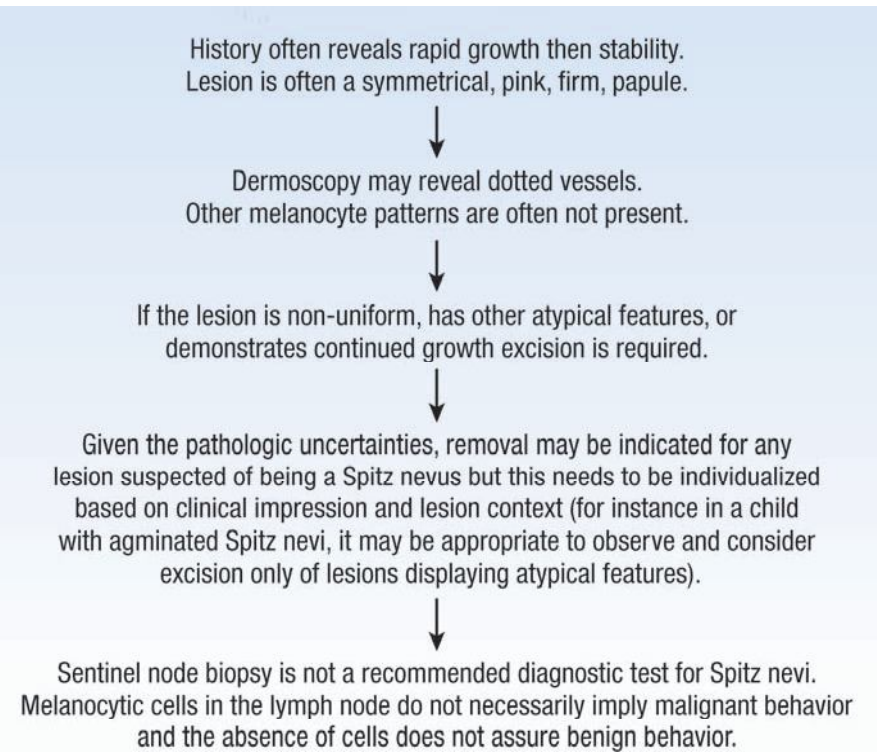
Spitz nevi can also present as widespread eruptive lesions or in a grouped manner as multiple agminated lesions consisting of red, red-brown, brown, or dark-brown papules or nodules, with a fine stippled surface (see Fig. 122-18C). Agminated Spitz nevi often occur in the early years of life within a background of congenital (sometimes acquired) macular pigmentation (nevus spilus) or occasionally within a hypopigmented plaque. Spitz nevi may also develop as single or multiple lesions in a large CNN.

The diameter of Spitz nevi ranges from several millimeters to several centimeters, the average being 8 mm in one series.[82] In 73 percent of patients in one series,[81] the tumor diameter was 6 mm or less, and in 94 percent of patients, the tumor diameter was less than 10 mm. Most cases are described as superficial papules or nodules, although subcutaneous involvement may occur.[87] In one series of 43 patients,[82] the anatomic location included the head or neck in 18, upper extremities in 9, torso in 9, and lower extremities in 7. Spitz nevi tend to spare palms, soles, and mucous membranes.

RELATED PHYSICAL FINDINGS There is no known association with other somatic abnormalities.

Laboratory Tests

HISTOPATHOLOGY Unlike ordinary nevi and melanomas, melanocytic cells in Spitz nevi are large—often twice the size of epidermal basal keratinocytes,[86] with prominent mononuclear or multinucleated giant cells in the epidermis and/or dermis (Fig. 122-19). Mitoses, usually few in number, are detected in one-half the cases,[88] whereas atypical mitoses are uncommon in Spitz nevi. In contrast to melanoma, the melanocytic cells in Spitz nevi show progressive maturation with increasing depth, becoming smaller and more similar to ordinary nevomelanocytes,[86,88] with the overall distribution of cells in the dermis being wedge-shaped, with narrowing of the wedge toward the subcutaneous fat.



▲ **FIGURE 122-17** Approach to the patient with Spitz nevus.

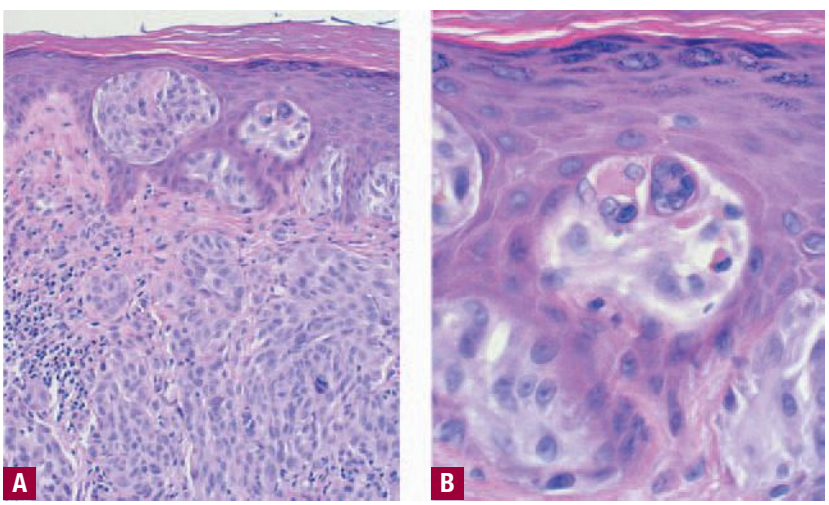
▲ **FIGURE 122-18** Spitz nevi. **A.** Pink plaque, which appeared de novo over an 8-week period, becoming more elevated with time, in the preauricular area of a 4-year-old white boy. **B.** Dome-shaped pink papule, which appeared de novo over a 2-week interval 4 months before, on the forehead of a 5-year-old white boy. **C.** Agminated Spitz nevi. Numerous grouped pink papules and plaques, appearing at age 6 months, on the face of a 4-year-old white boy.

Coalescent eosinophilic globules (Kamino bodies), periodic acid-Schiff–positive and diastase-resistant (resembling colloid bodies), have been reported in 60 percent of Spitz nevi[89] (see Fig. 122-19). Similar globules may be detected in 2 percent of melanomas and 0.9 percent of typical acquired nevi, but the globules are smaller in size, more difficult to find, single rather than coalescent, and commonly periodic acid-Schiff–negative.[89]

Melanocytic elements are usually arranged in well-circumscribed nests, although there may be permeation of the epidermis by single cells or small groups of cells. In those cases with epidermal nests, artifactual clefts are usually seen above the nests in half the cases, a finding rarely observed in melanoma.[81] The epidermis is usually hyperplastic, with elongated and bulbous pegs and knobs extending into the dermis, although thinning and even ulceration may occur rarely. The dermal inflammatory cell infiltrate may be slight or marked, band-like, and mainly at the base or patchy around blood vessels and/or intermixing with tumor cells. Although melanin was observed in all 13 patients originally described by Spitz,[86] more recent studies have determined that melanin was moderate in 10 percent of cases and heavy in 5 percent.[88]

Although the bizarre histopathologic features and frequent occurrence of dermal inflammation may cause diagnostic confusion, Spitz nevus usually can be differentiated from melanoma. The histologic features of Spitz nevus in children and adults are similar.

SPECIAL TESTS A subgroup of Spitz nevi have a gain of chromosome 11p and amplification or activation of H-RAS.[84] These markers are not routinely used in the clinical setting but may be helpful in the future for discriminating these nevi from other melanocytic neoplasias.



▲ **FIGURE 122-19** Histopathologic features of Spitz nevus (**A**) and higher magnification of the intraepidermal component revealing eosinophilic cytoplasmic changes (Kamino bodies) in several cells (**B**).

Differential Diagnosis (Box 122-6)

Complications

Misinterpretation of benign or malignant behavior of the lesion could result in unnecessary or insufficient treatment, respectively.

Prognosis and Clinical Course

The natural history of the Spitz nevus is largely unknown. Based on patients with eruptive Spitz nevi, it is clear that spontaneous regression can occur.[87] A

concern is that some lesions diagnosed as Spitz nevi may progress to melanoma or represent melanoma at the outset.[90]

Treatment

Complete excision with a clear margin of normal skin is generally sufficient treatment for Spitz nevi. Given the difficulty of confidently excluding the possibility of melanoma in certain cases, a wider margin of normal skin may be prudent for histopathologically worrisome lesions.[90] Incompletely excised lesions may recur in as many as 7 percent to 16 percent of patients.[82,91–93] Although some authors have advocated sentinel node biopsies in these lesions, this may only add to the confusion because Spitz nevus cells may be present in the regional lymph nodes but not necessarily indicate malignancy.[94] Management of patients who have numerous Spitz nevi requires individual judgment and periodic examination for new or unstable lesions.

Prevention

The role of UVR exposure in the development or progression of Spitz nevi is unknown.

NODAL NEVI

Epidemiology

Nevomelanocytes can be identified in lymph nodes with a frequency ranging from 0.3 percent to 7.3 percent in lymphadenectomies not related to melanoma and up to 22 percent in regional nodes removed because of melanoma.[95] When nevomelanocytes are evident in lymphadenectomies due to melanoma, it has been reported that 75 percent of the primary cutaneous melanomas had an associated nevomelanocytic nevus, often with congenital features.[96] A significant association has also been noted for the presence of cutaneous nevomelanocytic nevi in the zones of skin drained by lymph nodes that were found to include nevomelanocytes.[97] In most cases, the nevomelanocytes appear to be derived from common acquired nevi, but congenital nevi, blue nevi, cellular blue, and Spitz nevi have all also been reported to involve regional lymph nodes.[64]

Etiology and Pathogenesis

There are two prevailing theories as to the mechanism by which nevomelanocytes appear in regional lymph nodes.

NODAL NEVI AT A GLANCE

- A benign melanocytic neoplasia present in a lymph node. Nevomelanocytes are often located in the capsule but they may also be present in the parenchyma of the nodal tissue.
- Generally asymptomatic and found as a result of lymph node removal.
- Cells may be deposited passively into the node from a cutaneous melanocytic lesion. It is also possible that abnormal migration pathways result in the nevomelanocytes taking up residence in the nodes during embryonic development.
- The presence of these cells in nodal tissue creates difficulties for pathologists evaluating sentinel node biopsies.

The first theory is that during development, nevomelanocytes get trapped in the developing nodal tissues. Some support for this theory could be based on the fact that nodal nevi can be found in association with congenital nevi. This observation suggests that there is an opportunity for nevomelanocytes to be deposited during development. Further, blue nevus cells can be found in tissues such as prostate, cervix, vagina, spermatic cord, and seminal vesicles.[64] Thus, aberrant migration and differentiation of melanocytic cells do occur.

The second theory suggests that there may be passive transfer from the cutaneous lesion to the lymph node. Substances such as carbon, tattoo ink, and radioactive colloid are readily transferred to the draining lymph node. It is reasonable to assume that loosely adherent nevomelanocytes could also traverse the same path. In fact, nevomelanocytes have been noted in lymph channels.[64] Once in the lymph node, nevomelanocytes are generally identified in the capsule, but they can also be found in the parenchyma.[95] It is not known how nevomelanocytes get into the capsule, but it is reasonable to assume that these cells migrate from the parenchyma into the capsule. It is important to note that melanoma cells can also be found in the capsule,[98] so it is rational to assume that entry into the capsule is not limited to a developmental event. The fact that nevomelanocytes in regional lymph nodes are highly correlated with the presence of nevomelanocytic nevi in the skin, supports the concept that these cells arrive in the lymph nodes via dissemination from the benign cutaneous lesion.

Clinical Findings (Fig. 122-20)

HISTORY Generally, nodal nevi are identified in lymph nodes that are removed because of melanoma, but these benign cells are also identified in nodes removed for other reasons. Generally, the patient does not note symptoms related to the nodal nevus.

CUTANEOUS LESIONS Common acquired nevomelanocytic nevi, congenital nevomelanocytic nevi, blue nevi, and Spitz nevi have been noted to give rise to nodal nevi.[64]

RELATED PHYSICAL FINDINGS Due to concern for melanoma, patients should be

Lymph node often removed due to concern for melanoma, but could also have been removed for other reasons.

↓

Histopathologic evaluation is required. It is best to review the lesion in the skin draining to the node along with the node. Location of the nevomelanocytes and cellular appearance may be sufficient for diagnosis.

↓

Immunohistochemistry revealing a lack of proliferative component or high p16 level may help substantiate the benign diagnosis. Molecular PCR based tests do not generally differentiate between benign and malignant melanocytic cells.

▲ **FIGURE 122-20** Approach to the patient with nodal nevus. PCR = polymerase chain reaction.

Box 122-7

Differential Diagnosis of Nodal Nevi

- Melanoma
- Cells from other neoplastic source
- Foreign body deposit (tattoo ink, carbon)

evaluated for findings that might be worrisome for metastatic melanoma.

Laboratory Tests

HISTOPATHOLOGY Pathology often reveals nevomelanocytes largely confined to the nodal capsule. However, cells may also be noted in the parenchyma. These cells should bear resemblance to the cells in the cutaneous lesion. Lack of proliferative markers (Ki67) and possibly high levels of p16 immunohistochemistry markers support the benign diagnosis.[99]

SPECIAL TESTS The use of standard immunohistochemical tests may help identify the location and cellular features of the nevomelanocytes in the lymph node tissue sections. Reverse transcriptase–polymerase chain reaction tests do not discriminate benign from malignant melanocytic nodal disease.

Differential Diagnosis (Box 122-7)

Complications

Complications, such as scarring or lymphedema, may exist for the surgical procedure. A misinterpretation of benign nodal deposits as malignant could result in unnecessary regional lymph node dissection and treatment with systemic agents. An interpretation of malignant nodal cells as benign would not flag the patient as having a worse prognosis and may delay other treatments.

Prognosis and Clinical Course

If the lymph node deposits are determined to be benign, no further treatment is warranted.

Treatment

None required for benign nodal nevi.

LENTIGO SIMPLEX

Epidemiology

The frequency of lentigo simplex in children and adults has not been determined. There does not appear to be a racial or gender predilection. Lentigo simplex is the most common histopathologic pattern of darkly pigmented lesions excised from acral sites of darkly pigmented races.[28] Pigmented nail bands, noted in up to 20 percent of Japanese, may have histopathologic features of lentigo simplex.[100] For agminated lentigines, the population prevalence is unknown, but it is believed to be rare.

Etiology and Pathogenesis

The increased density of melanocytes in lentigines is presumably due to an underlying developmental or intrinsic defect in melanocyte homeostasis. In some lentigines, the presence of melanin macroglobules in melanocytes and keratinocytes suggests that defects affecting melanization pathways are also involved. The presence of lentigo simplex in association with somatic abnormalities in such diverse conditions as Peutz-Jeghers syndrome, LEPOARD syndrome (*l*entigines; *e*lectrocardiogram conduction defects; *o*cular hypertelorism; *p*ulmonary stenosis; *a*bnormalities of genitalia; *r*etardation of growth, and sensorineural *d*eafness), and LAMB/myxoma syndrome suggests that lentigo development may be influenced by a number of different genetic factors. For agminated lentigines, it is possible that chromosomal mosaicism plays a role in the development of the localized collection of lentigines.

Clinical Findings (Fig. 122-21)

HISTORY Unlike solar lentigines, lentigo simplex is thought to be largely UVR independent. Lentigo simplex may appear as early as the first decade and may occur anywhere on skin or mucous membranes.

Generalized lentigines may occur as an isolated phenomenon without known familial aggregation and first appear at birth, during infancy, or during adulthood. Familial clustering in an autosomal pattern also has been noted. A number of syndromes are recognized (see Chap. 73).

In Moynahan (LEOPARD) syndrome, lentigines are present at birth or shortly thereafter and may increase in number during childhood. In Peutz-Jeghers syndrome, numerous lentigines may be present at birth or appear during early childhood. Oral pigmentation usually persists in Peutz-Jeghers syndrome, whereas cutaneous lentigines usually fade after puberty. In LAMB syndrome, the lentigines on the lips and genital sites appear in early childhood and tend to persist.

Agminated lentigines first become manifest at birth or early childhood.

CUTANEOUS LESIONS Lentigo simplex usually is a sharply circumscribed, light-brown or dark-brown macule.

In Moynahan (LEOPARD) syndrome, lentigines occur on both sun-exposed and sun-protected sites, including genitalia, conjunctiva, oral mucosa, palms, and soles. In Peutz-Jeghers syndrome, lentigines are almost always present on the oral mucosa. Other common sites of involvement include lips, nose, eyelids, anus, nail bed, and dorsal and ventral surfaces of hands and feet.

LENTIGO SIMPLEX AT A GLANCE

- Includes a spectrum of melanocytic hyperplasias consisting of intraepidermal melanocytic hyperplasia and increased melanin formation. The extent of melanocytic hyperplasia can be quite variable, ranging from lesions in which the increased melanin content is notable but the increase in melanocyte number is marginal, to lesions in which accumulation of melanocytes is marked.
- Lesions consist of hyperpigmented macules and may be isolated, agminated (focal cluster), or multiple and present on skin, nails, and mucous membranes.
- May be congenital or acquired.
- Multiple lentigines may be associated with somatic abnormalities.
- Synonyms: simple lentigo, melanotic macule, lentiginosis. Other names for agminated lentigines include unilateral lentigines, partial unilateral lentiginosis, lentiginous mosaicism, and segmental lentiginosis.
- Other lesions in which epidermal melanocytic hyperplasia may be noted, and some overlap may exist with simple lentigines, include café-au-lait macules, melasma, and inflammatory/cytokine-induced proliferation.

Dermoscopy tends to reveal a simple well defined regular pigment network without any other dermoscopic findings, such as dots or globules, that might suggest junctional or dermal collections of nevomelanocytes.

↓

If lesions are multiple and in one focal location, agminated lentigines should be considered. Wood's light will help to exclude background hyperpigmentation that might indicate nevus spilus.

↓

If lesions are multiple and dispersed, consider possible associated syndromes and evaluate for associated abnormalities.

↓

If lesions are in an adult and in sun exposed (or tanning/UV box exposed) area, consider the possibility that the lesions are solar lentigines.

↓

A lesion not displaying uniform features, particularly if changing, needs to be considered for biopsy to exclude melanoma.

▲ **FIGURE 122-21** Approach to the patient with lentigo simplex. UV = ultraviolet.

Lentigines in the myxoma syndrome (LAMB) occur mainly on the face and genitalia as tan to black macules (Fig. 122-22). In centrofacial lentiginosis, the presence of pigmented macules is restricted to a horizontal band across the central face.

Agminated lentigines first become manifest at birth or early childhood as small, circumscribed, light-brown macules, 2 to 10 mm in diameter, confined to a localized area of the skin, often in a segmental distribution (Fig. 122-23) and frequently in a curvilinear or swirled pattern. Wood's lamp examination may be required to differentiate agminated lentigines from nevus spilus, because the macular background pigmentation is evident in the latter and absent in the former.

RELATED PHYSICAL FINDINGS If there is concern that the lentigines are part of a syndrome, further evaluation is appropriate, and should be guided by the physical findings and syndrome under consideration.

Laboratory Tests

HISTOPATHOLOGY Lentigo simplex consists of intraepidermal melanocytic hyperplasia in the basal layer of elongated epidermal rete ridges, without nest formation. At one end of the lentigo spectrum, lesions are more similar to café-au-lait lesions, in which the melanocyte number may only be minimally increased but pigmentary differences are marked; at the other end of the spectrum, the number of melanocytes is sufficiently increased to begin forming nests, appearing similar to a junctional nevus. Depending on the degree of keratinocytic hyperplasia, distinct separation from solar lentigo may not be possible based on histopathologic interpretation alone. Giant pigment granules (melanin macroglobules) may occur in lentigo simplex in isolation, and in association with multiple-lentigines (LEOPARD) syndrome.

In agminated lentigines, histopathologic studies reveal increased numbers of melanocytes in elongated epidermal rete ridges, similar to lentigo simplex, without nests of nevomelanocytes or cellular inflammation.

SPECIAL TESTS Mart-1, Mel-5, and DOPA histochemistry may be useful to demonstrate increased number of melanocytes confined to the basal layer and lacking junctional nest formation. If a syndrome is under consideration, imaging studies may be required.

Differential Diagnosis (Box 122-8)

Complications

There are no known complications from lentigo simplex. Complications arise from the associated syndromes. Atypical varieties of lentigo simplex (in any anatomic site) may be potential precursors or masqueraders of melanoma.

Prognosis and Clinical Course

The natural history of isolated lentigo simplex is not known. Once developed, the lesions are presumed to be relatively stable. There is no convincing evidence that lentigo simplex evolves to a nevomelanocytic nevus. As with any process in which melanocytes are present (including normal skin), it is possible for melanoma to arise in a lentigo, but an elevated risk has not been demonstrated conclusively for lentigo simplex.

The long-term course and malignant potential of agminated lentigines are unknown.

Treatment

There is no need to treat benign-appearing lentigo simplex. Cosmetic removal may be achieved with cryotherapy or

▲ **FIGURE 122-22** Lentigo simplex. **A.** Acquired darkly pigmented lentigines on the vulva of a 13-year-old white girl who has *l*entigines, *a*trial myxomas, *m*ucocutaneous myxomas, and *b*lue nevi (LAMB, myxoma) syndrome. **B.** Multiple lentigines on the lips of the same patient. This patient died in her mid-20s of a malignant schwannoma.

other destructive approaches such as Q-switched laser. However, caution must be taken to ensure the lesion being treated is benign. Lesions that are significantly unusual, irregular, asymmetric, or changing in shape should be examined histopathologically to exclude melanoma. Wood's lamp examination is useful in defining margins of lentigo simplex.

Until the long-term course of agminated lentigines is known, it may be prudent to recommend periodic examinations to detect the earliest signs of possible malignant evolution.

Prevention

UVR is clearly associated with the development of solar lentigines, but its role in the different types of simple lentigines is not known. However, it is rational to limit UVR overexposure.

SOLAR LENTIGO

Epidemiology

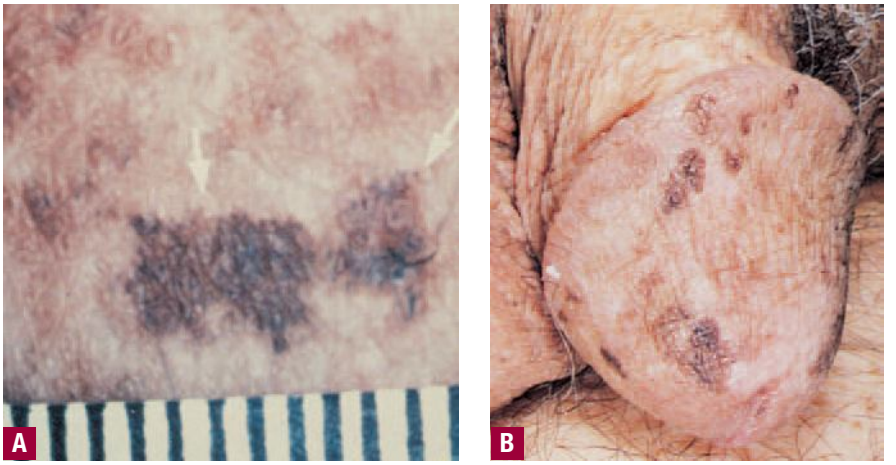
The prevalence of solar lentigines is correlated directly with increasing age, and they are present in 90 percent of white people over 60 years of age.[101] Solar lentigines are common in individuals who sunburn easily and do not tan, whereas they are uncommon among people who have darkly pigmented skin.[102]

Lentigines may be induced by photochemotherapy [psoralen and ultraviolet A light (PUVA) lentigo], occurring in 40 percent to 50 percent of patients an average of 5.7 years after starting therapy, their frequency and severity directly attributable to the total number of treatments (Fig. 122-24; see Chap. 239).[102] Darkly pigmented skin is associated with the lowest risk for PUVA-induced or solar-induced lentigines.[102] Lentigines have been associated with UVA tanning bed use.[103]

Lesions similar in gross and microscopic appearance to solar lentigo, freckle (ephelis), may occur in children and young adults.[104] They may appear within the first 5 years of life, tend to aggregate in families, and are significantly associated with red hair; their location and density correlate with sun sensitivity and sun exposure. The presence of freckles has been associated with a 2.5-fold increase in the rate of sunburn susceptibility and poor tanning

SOLAR LENTIGO AT A GLANCE

- Solar lentigo is distinguished from lentigo simplex histopathologically on the basis of shape and extent of epidermal hyperplasia. The epidermal hyperplasia is often more prominent in solar lentigines and may include "bud-like" structures at the base of rete ridges.
- Solar lentigines appear as circumscribed pigmented macules occurring singly or as multiple lesions and present on the skin surface exposed to natural or artificial sources of ultraviolet radiation. Distinct subtypes exist and include the ink spot lentigo.
- Most solar lentigines occur in adults.
- Solar lentigines are benign but caution must be taken to discriminate benign lesions from lentigo maligna.
- Outdated synonyms: sun-induced freckle, liver spot, lentigo senilis, and senile lentigo.



▲ **FIGURE 122-24** Photochemotherapy [psoralen and ultraviolet A light (PUVA)]-induced lentigines on the buttock (**A**) and penis (**B**) of a 57-year-old white man who had received PUVA for psoriasis several times per week for 5 years. The PUVA lentigines appeared between 1 to 2 years after PUVA therapy was begun. The current recommendation is to shield the male genitalia during PUVA therapy to prevent epithelial tumors of the penis and scrotum.

response and a three-fold greater likelihood of a lower minimal erythema dose in people who mostly burn and tan minimally or not at all.[105] The presence of dense sun-induced freckling increases the estimated risk for melanoma by three- to fourfold.[106]

Etiology and Pathogenesis

Solar lentigines are thought to represent a marker of intermittent high-intensity UVR, cumulative UVR, and/or a unique susceptibility to the proliferative, stimulatory, and/or mutagenic effects of UVR. Given the hyperplasia of both the keratinocytes and melanocytes, the primary defect in solar lentigines could be in either cell type eliciting a secondary proliferative response in the other.

There is a pronounced link between UVR exposure and the development of lentigines. Single exposures of experimental UVB radiation (320 mm) that is 6 to 10 times the minimal erythema dose induces "freckling" in susceptible individuals.[107] Phototoxic doses of PUVA may lead to the development of lentigines 6 to 8 months later.[108] In addition to the total dose of UVR received during photochemotherapy, individual susceptibility factors to lentigo development include race, age, and burning/tanning response to sunlight.[102]

Supportive of the underlying mutation being present in the melanocytes is the finding that epidermal melanocytic cellular atypia persists in lentigines developing in patients receiving chronic photochemotherapy for 1 to 2 years or longer after therapy is discontinued.[102]

In xeroderma pigmentosum (XP), in which patients have an increased sensitivity to UVR, hyperpigmented macules develop on light-exposed skin within the first 5 years of life (see Chap. 109), and these lesions demonstrate hyperplasia of variably atypical epidermal melanocytes (i.e., atypical lentigines). In one series of XP patients from Japan,[109] lentigo maligna melanoma was the predominant melanoma type, suggesting an association between this tumor subtype, sensitivity to UVR, and the presence of UVR-induced atypical solar lentigines, and supportive of the underlying mutation being in the melanocytic lineage.

Clinical Findings (Fig. 122-25)

HISTORY Solar lentigines appear as acquired lesions, generally in fair-skinned individuals, on sun-exposed skin surfaces. For the majority of solar lentigines, it is assumed that once present, they remain stable.

CUTANEOUS LESIONS Solar lentigo occurs as a pigmented macule on skin exposed to natural sunlight or artificial sources of UVR, usually in the presence of similar lesions in the same location (Fig. 122-26). Lesions may be tiny (< 1 mm in diameter) or large (up to a few centimeters in diameter), with a tendency to confluence in severely sun-damaged skin and with smooth or irregular outlines. Lesions are usually light brown, but varieties of solar lentigo are jet black, similar to an India ink stain (ink spot lentigo). Although solar lentigo usually occurs on sun-exposed skin, identical-appearing lesions may occur on sun-protected sites (including the penis and buttocks) that have been exposed to photochemotherapy (see Fig.

Dermoscopically these lesions are of uniform color and may have a prominent network pattern or a diffuse uniform very light brown pigmentation. The borders may have a jagged shape, but the interface between lesion and normal skin is generally visible. These lesions may occasionally be difficult to differentiate from a junctional nevus or a flat seborrheic keratoses.

↓

Solar lentigines are more likely to be found on fair skinned individuals with advancing age.

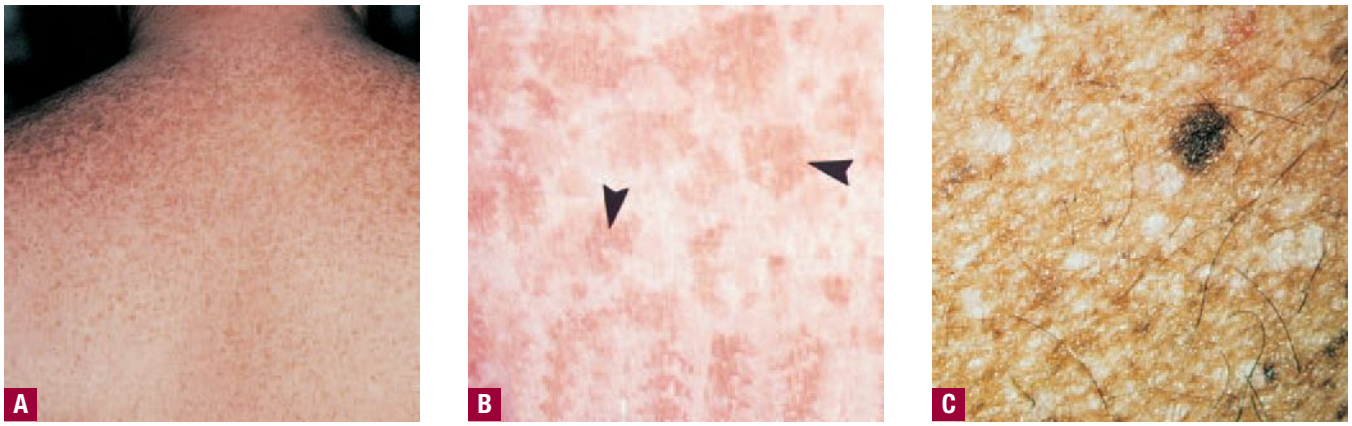
↓

The lesions should be found in areas of significant UVR exposure. Important to keep in mind, these lesions may even be present on genital skin in the setting of PUVA or other intense UVR exposures.

↓

Lesions appearing different than the others and changing, especially if non-uniform, need to be considered for biopsy to exclude melanoma (particularly the lentigo maligna subtype). On the face, dermoscopic structures that increase concern for melanoma include asymmetric follicular pigmentation, gray pigment network, and annular/granular and rhomboidal structures.

▲ **FIGURE 122-25** Approach to the patient with solar lentigo. PUVA = psoralen and ultraviolet A light; UVR = ultraviolet radiation.



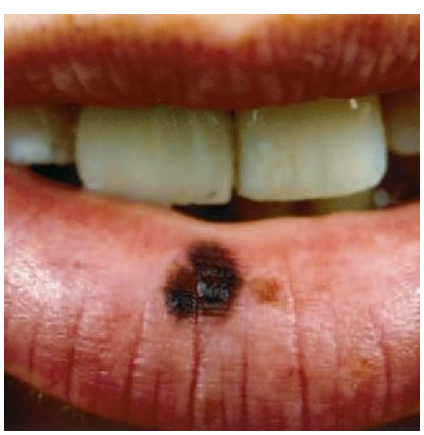
▲ **FIGURE 122-26** Solar lentigo. **A.** Uncountable solar lentigines on the back of a 30-year-old white man, appearing initially during early childhood after multiple sunburns. **B.** High magnification of lentigines in (**A**) showing light-brown macules with markedly irregular outlines. **C.** Solar lentigines on sun-damaged dorsal hand skin (hypopigmentation, wrinkling, and telangiectasia) of an elderly white man.

122-24). When examined by dermoscopy, solar lentigines reveal a uniform reticular network.[110] Lentigines in patients receiving PUVA and in individuals who have XP are often darkly and/or irregularly pigmented.

Solar lentigines not apparent in visible light may be visualized using Wood's lamp illumination.

The oral-labial melanotic macule has gross morphologic characteristics similar to solar lentigo (Fig. 122-27), but its relation to a sun-sensitive phenotype or excessive sun exposure has not been well documented.

A clinical distinction is made between a freckle (ephelis) and a solar lentigo. Freckles are common on the central face and often first noted in early childhood, presumably developing after significant sun exposure and are said to fade or even disappear when sun exposure is discontinued. Unfortunately, there are no longitudinal studies of ephelides or solar lentigines that document gross morphologic or time-course differences that would reliably allow a clinical distinction between ephelides and solar lentigines. According to L-3, 4-dihydroxyphenylalanine (DOPA) studies on epidermal sheets, ephelides have been reported to show increased melanogenesis but decreased melanocyte number, which implies a different pathologic basis.[107,111] However, counting melanocytes in DOPA-incubated epidermal sheets is unreliable for pigmented lesions, and these early studies must be questioned. Studies in DOPA-incubated tissue vertical sections demonstrate that melanocytes are increased in "ephelides" in children and young adults, similar to solar lentigines.[44,110]



▲ **FIGURE 122-27** Labial melanotic macule, appearing 5 years earlier, on the lower lip of a 26-year-old white woman.

RELATED PHYSICAL FINDINGS Patients with solar lentigines are more likely to be fair skinned, particularly those with red hair and or lighter eye color. Along with the lentigines, increased solar damage may be noted and other lesions such as idiopathic guttate hypomelanosis, actinic keratoses, and seborrheic keratoses may be present. The presence of solar lentigines is a risk factor for melanoma, basal cell cancer, and squamous cell cancer.

Laboratory Tests

HISTOPATHOLOGY Solar lentigines reveal elongated epidermal rete ridges with club-shaped or bud-like extensions, frequent branching and fusing of rete ridges, a thinned or atrophic epidermis between rete ridges, and increased numbers of epidermal melanocytes without nesting. The microscopic appearance suggests a concurrent proliferation of keratinocytes and melanocytes.[112] There is a scant to moderate perivascular mononuclear cell infiltrate in the dermis, usually associated with scattered melanin-laden macrophages.

Histopathologic characteristics of the labial melanotic macule (labial lentigo) are similar to those of solar lentigo, showing melanocytic hyperplasia but without cellular atypia. The presence of melanocytic hyperplasia in labial melanotic macule is not a uniform finding in all studies.

SPECIAL TESTS Mart-1 and DOPA histochemical studies may be useful to demonstrate increased number of melanocytes confined to the basal layer and a lack of junctional nest formation.

Differential Diagnosis (Box 122-9)

Complications

A potential complication is the discovery that an atypical solar lentigo is actually melanoma (often of the lentigo maligna variety).

Prognosis and Clinical Course

Solar lentigines may appear at any time of life. A solar lentigo may enlarge, darken, and become stable over time, but longitudinal studies of solar lentigines are lacking. It is possible that once formed, solar lentigines may persist indefinitely

Box 122-9

- Lentigo maligna

or fade slightly with time. Solar lentigines may be a heterogeneous population that includes lesions that fade and lesions that do not fade after UVR avoidance. The presence of these lesions suggests an increased risk for melanoma and nonmelanoma skin cancers.

It has been proposed that some varieties of lichenoid keratosis (see Chap. 113) may be due to an acute inflammatory reaction targeting the solar lentigo, and that resolution of lichenoid keratosis may cause regression of the associated lentigo.[114]

The long-term course of atypical varieties of PUVA lentigo is unknown, but it is clear that PUVA lentigines (see Fig. 122-24) may persist 1 to 2 years or longer after therapy is discontinued[102] and that cellular atypia of epidermal melanocytes in these lesions may persist as well. It is also clear that these patients may be at increased risk for melanoma[115] and should be followed periodically for life.

Lentigo maligna (see Chap. 124) may masquerade as a solar lentigo early in its development or, alternatively, may evolve from a pre-existing solar lentigo. A solar lentigo not matching the patient's other lentigines and/or enlarging/darkening out of step should be examined histopathologically or followed closely.

Treatment

Solar lentigo usually requires no therapy, but importantly, its presence indicates sensitivity and/or excessive exposure to UVR. Bleaching creams containing hydroquinone are usually not effective. Cryotherapy or other superficial destructive techniques (such as Q-switched laser) may be an option if the lesion is clearly benign, but lesions may recur after therapy.

Prevention

It may be possible to prevent further solar lentigines by reducing sun exposure. This may be accomplished through avoidance, protective clothing, and sunscreens. Optimally, these measures should be initiated during early childhood and continued throughout life.

CHAPTER 123

Atypical Melanocytic Nevi

Margaret A. Tucker

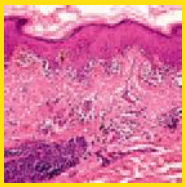
EPIDEMIOLOGY

The term *atypical melanocytic nevi* includes several clinical entities, including the common atypical dysplastic nevi, and rare atypical Spitz or spitzoid nevi, atypical genital nevi, and other unusual melanocytic nevi.[1] This chapter will focus on the common atypical/dysplastic nevi, which are relatively frequent melanocytic neoplasms.

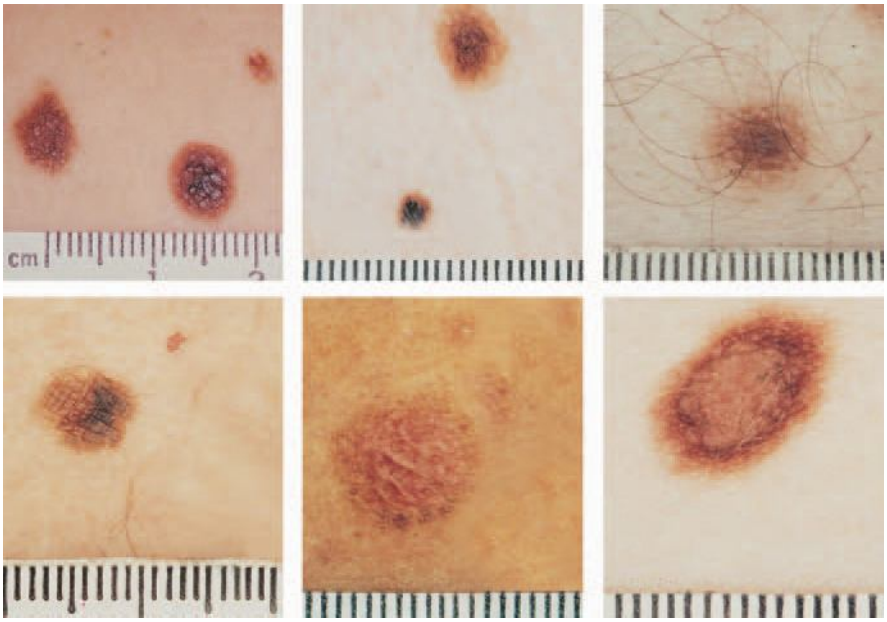
Atypical nevi were first recognized as distinct pigmented lesions during the clinical assessment of melanoma-prone families.[2] The nomenclature associated with these lesions also includes B-K moles (recognizing the first two families described whose surnames began with B and K),[2] familial atypical multiple mole and melanoma syndrome,[3] atypical mole syndrome,[4] Clark's nevus,[5] atypical moles, and nevus with architectural disorder (with varying degrees of melanocytic atypia).[6] The nomenclature has been contentious in the past. The term *dysplastic nevus* (DN) is more frequently used at present, both for clinical and histologic diagnoses,[7,8] and it is the personal preference of the author. Therefore, the term will be used throughout this chapter.

The usual clinical criteria for the diagnosis of a DN are two obligate features: Diameter in one dimension at least 5 mm and a prominent flat component, and two of three other features: Irregular, asymmetric outline, indistinct borders, and variable pigmentation (Fig. 123-1).[9] The histologic features include the presence of an immature or disordered growth pattern with a lymphocytic host response and random cytologic atypia in melanocytes (Fig. 123-2).[10] Multiple studies have demonstrated that the clinical

ATYPICAL/ DYSPLASTIC NEVI AT A GLANCE



- Prevalence among Caucasian young adults roughly 10 percent; varies by population
- Flat (totally or partially), large (> 5 mm) lesions with irregular shape, indistinct borders, and variable pigmentation
- Risk markers for melanoma and precursors of melanoma
- Most frequent on sun-exposed areas, especially intermittently exposed, such as back
- Associated with large numbers of common acquired nevi
- Majority of lesions will involute and disappear over time
- Histologic features include presence of immature, disordered growth pattern with a lymphocytic host response and random cytologic atypia in melanocytes



▲ **FIGURE 123-1** Atypical nevi have two obligate features: diameter in one dimension at least 5 mm and a prominent flat component, and two of three other features: irregular asymmetric outline, indistinct borders, and variable pigmentation.

and histologic criteria are each reproducible across observers.[11–14]

Most of the information on the epidemiology of DN has been obtained from studies of melanoma etiology. In virtually every study that has assessed risk of melanoma associated with DN, these nevi are associated with increased risk of melanoma.[15] Most of the epidemiologic studies have used the clinical diagnosis of DN as the risk factor analyzed. DN occur in approximately 10 percent of the adult populations of northern European descent based on the results of multiple case-control studies evaluating risk of melanoma associated with these lesions.[15] Among studies, the prevalence of DN in control populations has ranged from 7 percent to 24 percent. The studies occurred in different geographic regions, with varied control selection, and somewhat different criteria for the clinical diagnosis of DN. Given the differences in exposures and selection criteria for both study participants and nevi, the studies are remarkably consistent.

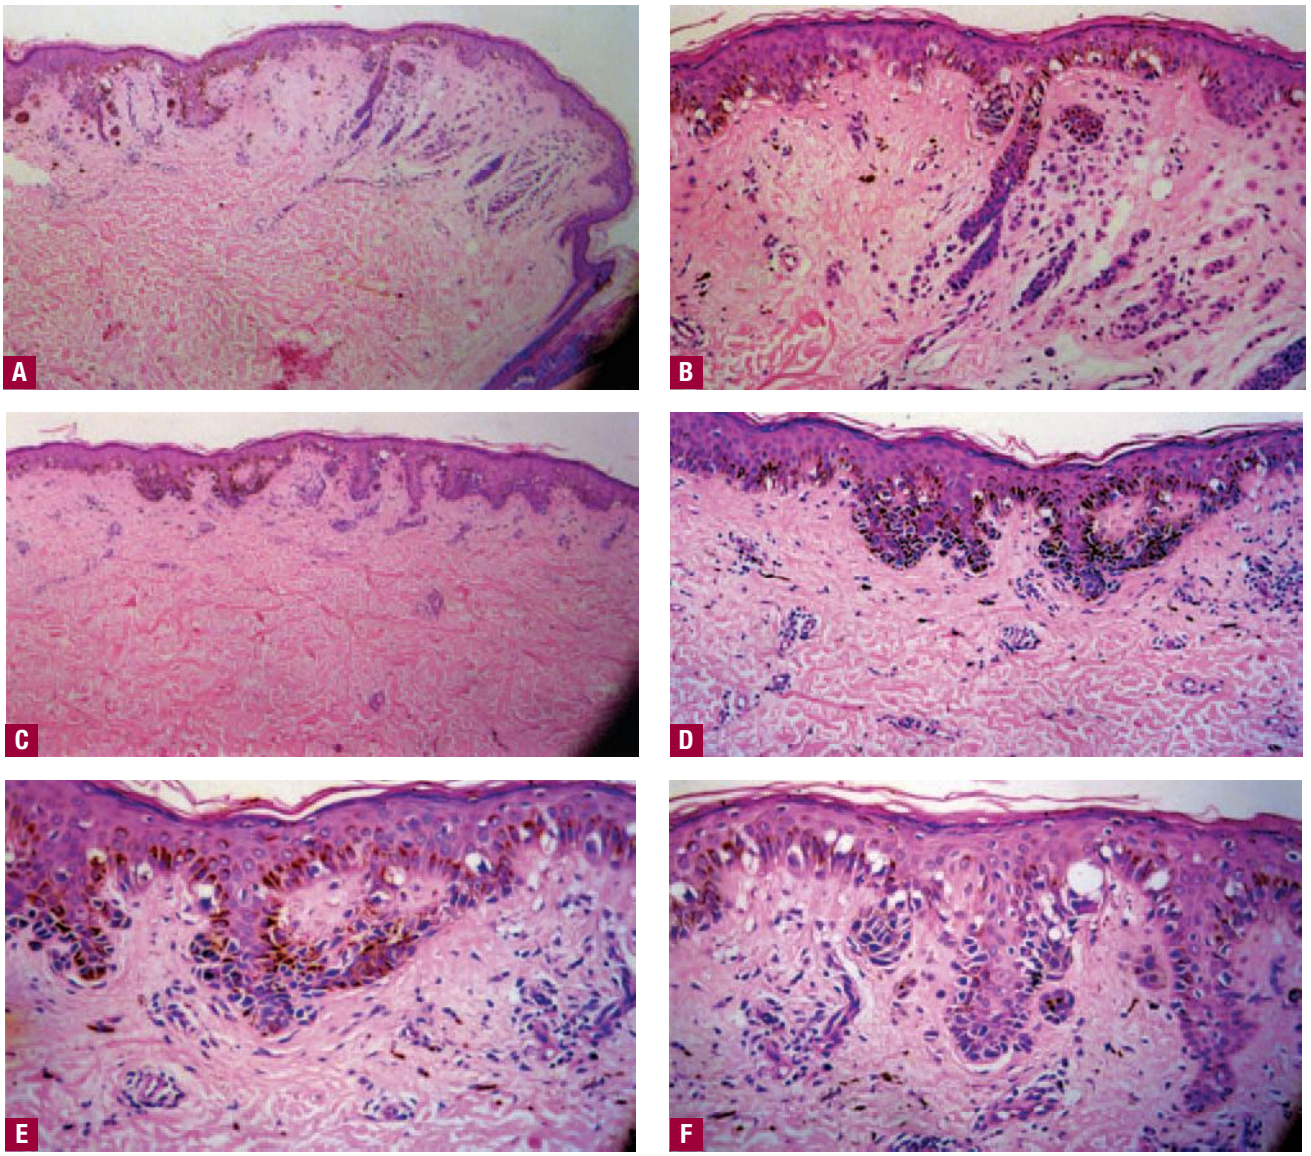
Limited data on the population prevalence of these lesions exist, and geographic and racial differences are likely. One early cross-sectional study in a New Zealand cohort (independent of melanoma) revealed DN in 9 percent of European descent adults.[16] A joint case-control study of nevi and melanoma in Australia and the United Kingdom demonstrated that DN were three times more frequent in the Australian controls (6 percent) than in the British controls (2 percent).[17] There are a few case reports of DN in Japanese, primarily in melanoma-prone families.[18]

DN are frequently found in melanoma-prone families in North America, Europe, and Australia.[19–27] They appear in the majority of Northern European families (from England, France, Holland, North America, Scotland, Sweden) and, to a somewhat lesser extent, in Spanish and Italian families. One of the differences in the Mediterranean families is that the nevi tend to be somewhat smaller than the 5-mm diameter criterion and may not be counted as dysplastic.

ETIOLOGY AND PATHOGENESIS

The etiology of DN is largely unknown, but there appears to be a genetic component of risk. DN occur in a familial pattern; limited segregation analyses suggest an autosomal dominant transition of the trait.[28] To date, no germline susceptibility genes have been identified for these lesions. Early on, it was hypothesized that melanoma and DN represented pleiotropic effects of a single gene.[29] After the first major melanoma susceptibility gene, cyclin-dependent kinase inhibitor 2A (*CDKN2A*), was identified, this hypothesis could be directly tested. Within melanoma-prone families with identified mutations in *CDKN2A*, DN do not consistently co-segregate with the mutation in the family.[30,31] This observation implies that the alteration in *CDKN2A* associated with risk of melanoma is not causal for DN. Within families having *CDKN2A* germline mutations, DN also appear to be an independent risk factor for melanoma.[22,31] Germline mutation testing of several other candidate genes for melanoma (e.g., *PTEN*, *BRAF*, *CDK4*) in individuals with DN, but not necessarily melanoma, has also not found mutations in the candidates selected.[32] Germline polymorphisms in *BRAF* were also not related to nevi or freckles in another study.[33] Although two groups have found evidence for linkage of a gene for increased number of nevi in the region around *CDKN2A* in twin studies,[34,35] a specific gene that is mutated has not yet been identified. One group also evaluated "atypical mole count" and found some areas of modest interest on chromosomes 1, 6, and X.[35] It is likely that DN, like melanoma, is a complex, heterogeneous trait.

One author has hypothesized that a single mutation in melanocyte precursors would be sufficient to explain the pathogenesis of nevi (not specifically DN).[36] Detecting novel characteristic somatic mutations in the atypical melanocytes within DN has been difficult,



▲ **FIGURE 123-2** The histopathology of the lesion shown in Figure 123-10. **A.** The low-power view shows a dermal nevus with dysplasia. **B.** A closer view of the dysplasia at the shoulder of the dermal nevus. **C.** Another area of dysplasia. **D.** On closer view, there is an increased number of melanocytes without an apparent increase in keratinocytes, with the melanocytes clustered on the sides and the ends of the retia. The nuclei of the melanocytes are quite atypical. **E.** At higher power, the nuclei of the melanocytes are atypical and enlarged, characteristic of epithelioid melanocytic dysplasia. **F.** Another area of the lesion with melanocytes in linear array, characteristic of lentiginous melanocytic dysplasia. The melanocytes are not as enlarged as in the area of epithelioid dysplasia. With > 30 atypical melanocytes and the level of disorganization of the architecture, the lesion is classified as severely dysplastic. (Photomicrographs used with permission from Wallace H. Clark, Jr.)

even with microdissection, because of the small clusters of atypical melanocytes. On account of this technical difficulty, data are available for relatively sparse numbers of lesions. For instance, in a report assessing *BRAF* V600E (formerly V599E) mutations in 77 nevi, mutations were found in 82 percent of all nevi, but only five DN were included.[37] Among these, four (80 percent) had the mutation. Another method for evaluating V600E, the ligase detection reaction, does not require microdissection and can be performed on paraffin sections of formalin fixed tissue.[38] This method has been used to evaluate the presence of mutations within 6 DN, half of which had the V600E mutation in *BRAF*. Based on limited data, although the V600E mutation occurs early in melanocyte tumor progression (in benign nevi), the mutation is not distinctively associated with DN, nor does it appear to be more frequent than in common nevi.

Somatic mutations in *NRAS* have also been described in melanomas and in nevi.[39,40] These mutations are found in lesions that do not have *BRAF* mutations. There is a specific activating mutation in codon 61 of *NRAS* that was evaluated in Swedish individuals with germline *CDKN2A* mutations. Seven DN, 21 melanomas, and two common acquired nevi were studied. All but one of the melanomas and five of the seven DN had the *NRAS* mutation; neither of the common acquired nevi did.[39] An earlier study using microdissection in 13 common nevi and nine DN showed hemizygous deletion in the region of p16 in seven of nine DN and in none of the common nevi.[41] In a similar manner, three of seven of the DN had hemizygous loss in the region of p53; all three also had deletions in the region of p16. None of the common nevi had hemizygous loss in the p53 region.

Senescence is usually driven by telomere shortening and is associated with increased expression of p16, among other tumor suppressors. One group re-

cently explored whether *BRAF* mutations, particularly V600E, in nevi were associated with senescence.[42] They measured activity of senescence-associated acidic β-galactosidase, a common senescence marker, and p16 in congenital (not dysplastic) nevi and in melanocytes transduced with lentivirus expressing V600E. They found that senescence-associated acidic β-galactosidase was always expressed in the nevi (n = 23) and in 80 percent of the cultured melanocytes. All of the nevi had some melanocytes expressing p16, but none showed upregulation of p21 and p53. Eight of the congenital nevi had V600E mutations; the pattern of p16 expression was heterogeneous and similar in lesions with and without V600E mutations. These findings suggest that other mechanisms in addition to p16 are important in the growth arrest of congenital nevi.

Several lines of evidence suggest that sun or ultraviolet light (UV) exposure is important in the etiology of DN. First, the lesions occur most frequently in sun-exposed areas, particularly in those intermittently exposed, but DN may also occur in unexposed areas.[19,44–47] The most common area for DN is on the trunk, primarily the back (Fig. 123-3; see eFig. 123-10.1 in on-line edition). There is relative sparing of the more sun-protected lateral thoracic regions and the inner aspect of the arms. Fewer DN occur in doubly covered areas such as on the buttocks. In a comparison of Australian and British controls from a joint case-control study, the prevalence of DN was three times higher overall in the Australians, but the prevalence of nevi on non–sun-exposed areas was the same.[17] Second, several studies have also demonstrated, to varying degrees, that individuals with DN report more frequent sun exposure and sunburns, especially before age 20, than individuals without DN.[48–50] Individuals who tan well appear to develop fewer DN. Third, based on longitudinal studies of melanoma-prone families, individuals with DN who use sun protective measures consistently develop fewer new nevi, and the dysplastic and common nevi they have are more likely to involute and disappear.[47] Sun-protected children in these high-risk families also develop fewer nevi. None of the existing data, however, prove causality between UV exposure and DN. Over time, some of the cohort studies of nevi in children from the general population may yield important information about the etiology of DN.

▲ **FIGURE 123-3** **A.** A back view showing the distribution of dysplastic nevus and lesion to lesion variability, with an increased number of common acquired nevi also. **B.** A closer view of a cluster of lesions marked as #2 on the back. The lesions are different sizes, colors, shapes, with differing amounts of asymmetry, and indistinct borders. Only the largest lesion meets all of the criteria for a clinical dysplastic nevus.

Clinical Findings (Fig. 123-4)

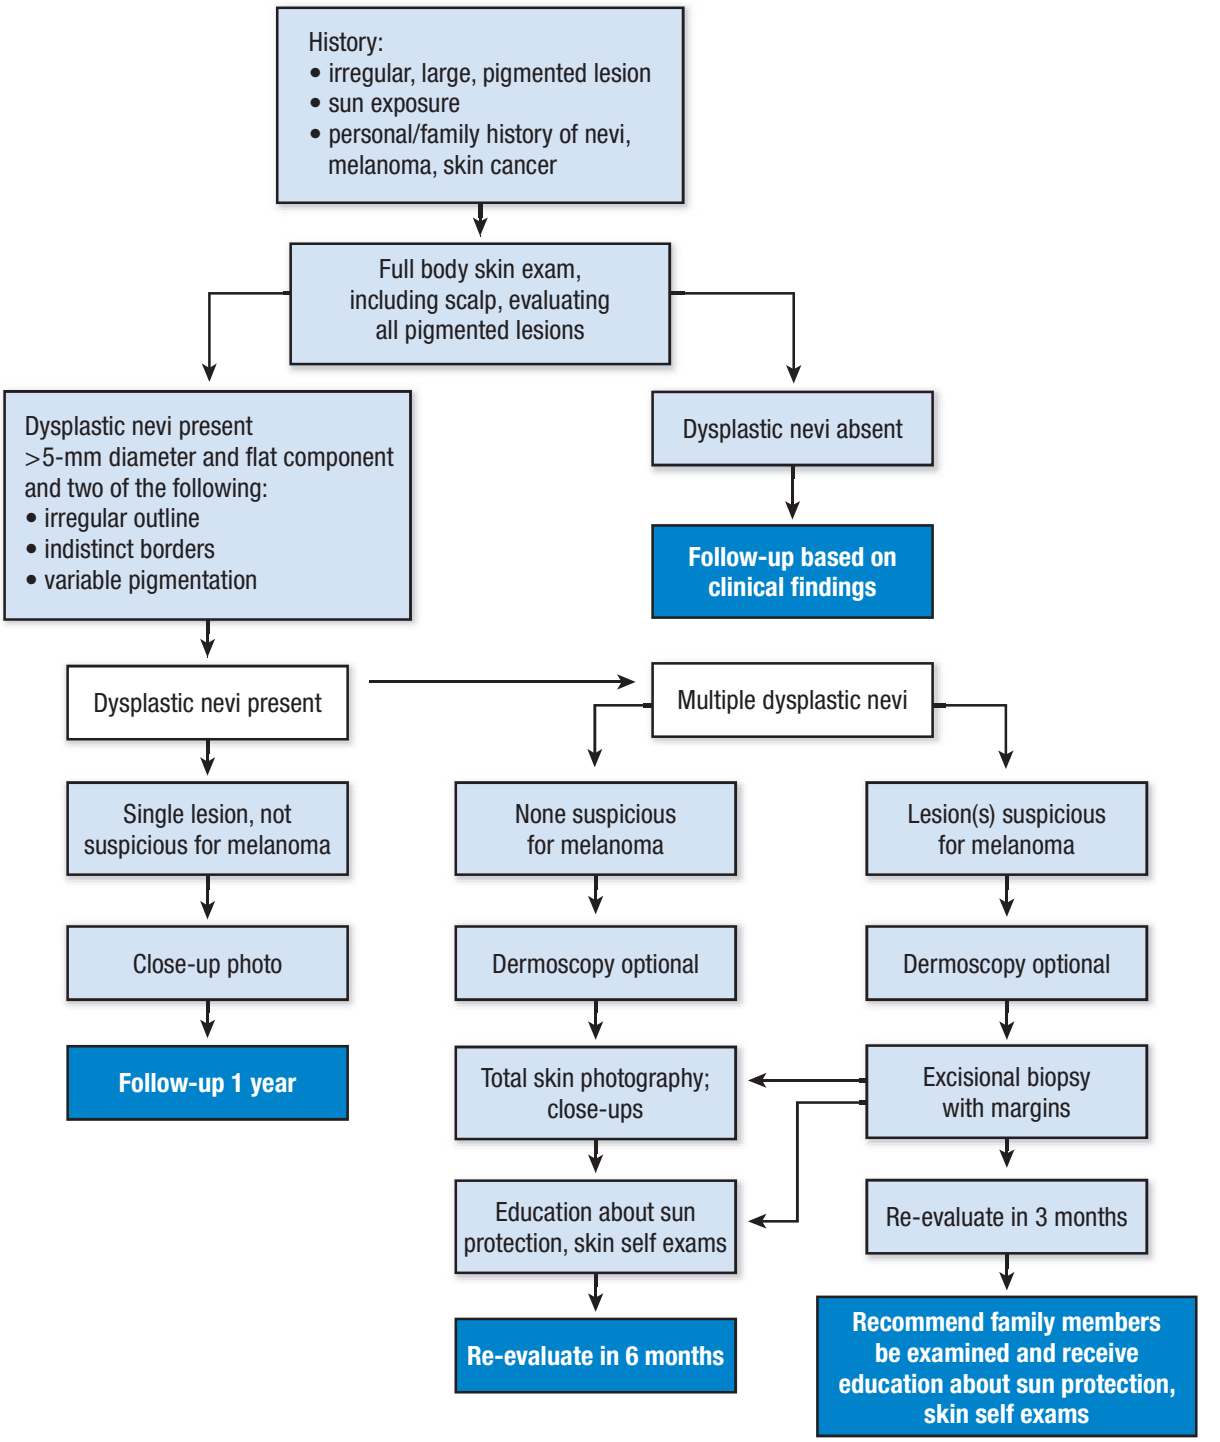
History

Many individuals with DN come to the attention of a clinician because they are worried about a changing mole. These individuals should be asked about their sun exposure patterns, their personal and family history of melanoma, other skin cancers, and other nevi. Most individuals with multiple DN consider themselves "moley" and often have "moley" family members. They will often report they have been "very moley all of their life." It is useful to ask if their moles changed during adolescence (puberty) or pregnancy.

Knowing the individual's sun exposure is important to understand both their nevus pattern and also, associated melanoma risk. Sun exposure patterns have several components. Although sun exposure at an early age is clearly a risk factor for nevi and melanoma, adult exposure is also important.[51] The practitioner should elicit residential history (e.g., ever lived in the southern half of the United States or in very sunny areas); recreational history (e.g., place and types of exposure); occupational exposure; sunburn (bad blistering) history; and tanning bed/solarium use. Individuals who burn easily may alter their exposure patterns as they age to minimize burning as they age. Time of day of exposure is also clearly important, as is shade-seeking behavior. Understanding current and past sun exposure patterns or sun-seeking behavior also helps personalize sun protection education.

Past history of melanoma or other skin cancer identifies individuals who have already had the exposure to make cancers and are at increased risk of developing another. Individuals who have had one melanoma are at substantially increased risk of developing another primary melanoma, especially within the first 5 years.[52] During this time period, individuals in the general population with melanoma have a 10-fold increased risk of melanoma. Having multiple nevi, especially DN, is one of the risk factors identifying those most likely to develop another primary melanoma.[53] A previous history of nonmelanoma skin cancer approximately doubles the risk for melanoma, especially in older men.[54] Members of melanoma-prone families with DN are at quite high risk of developing melanoma.[47] The risk of melanoma in individuals with multiple DN without a personal or family history of melanoma is also elevated,[9] but probably not as high as that of someone with such a history. It is important to know whether the patient has had multiple excisions of nevi in the past; if so, the current exam will not reflect their original nevus pattern. It is likely that their most atypical or largest nevi may have been removed; the pathology reports from these lesions are often quite useful. Despite the concern about melanoma in individuals with DN, most of these people will never develop melanoma.

For a specific lesion of concern, it is helpful to obtain information about the time period over which it has changed, what brought it to their attention, and whether there are sensations associated with it. It is also important to know if other lesions are also changing, because DN can have "bursts of activity" when

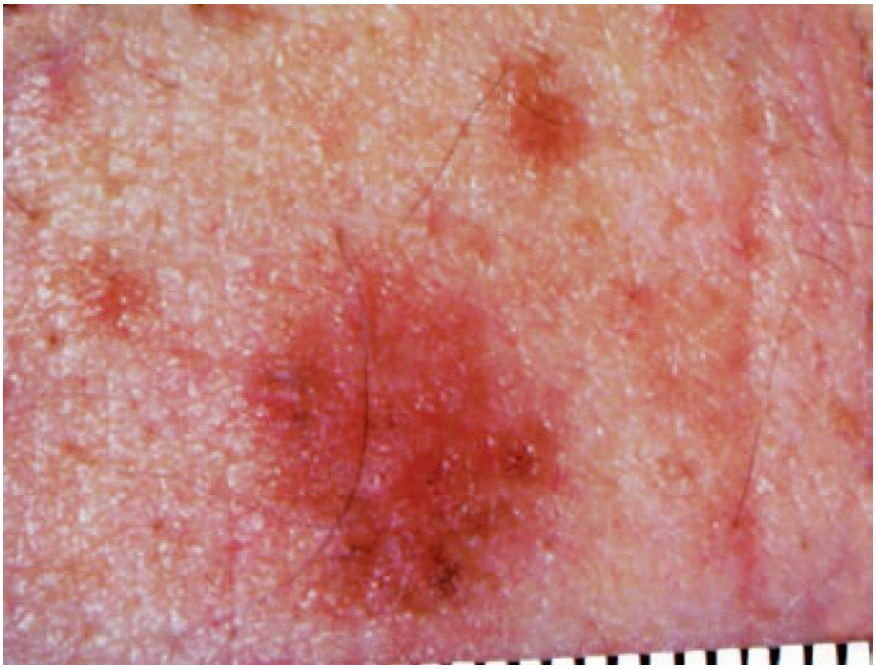


▲ **FIGURE 123-4** Approach to the patient with dysplastic nevi.

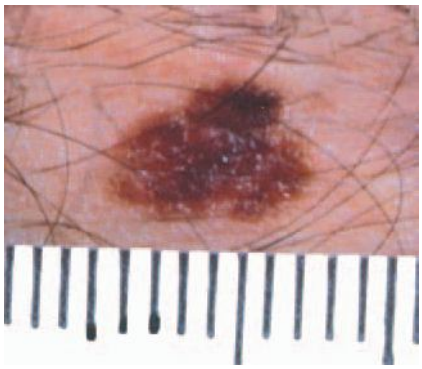
multiple lesions are changing. The reasons for the increased rate of change are not understood. Anecdotally, the changes can occur after increased sun or UV exposure (see Figs. 123-9 and 123-10), or in times of hormonal/growth changes such as puberty and pregnancy.[47]

Cutaneous Lesions

DN are large, flat, asymmetric lesions with irregular outline and variable coloration (see Fig. 123-1). Within an individual, there is lesion-to-lesion variability, but there tends to be some consistency in the appearance (see Fig. 123-3B). Between individuals, even within the same family, there can be very broad differences in appearance of DN.[47] Any specific lesion needs to be assessed in the context of where it is in its natural life history. By usual clinical criteria, to be a DN, the lesion must be at least 5 mm in one dimension. Some groups have used other sizes, such as 5 mm in all directions, 7 mm in diameter, or 8 mm in diameter. The most commonly accepted size now is 5 mm in at least one diameter. The requirement of 5 mm in all directions forces a relative symmetry which is not frequent in these lesions. DN tend not to be circular or smoothly ovoid. A DN must also have a flat component, which may be the dominant part of the lesion or might only be a remaining shoulder of the lesion (Fig. 123-5; see Fig. 123-1). Often, DN develop a somewhat "pebbly" surface, with several small papules (Fig. 123-6;



▲ **FIGURE 123-5** The largest diameter of this lesion is approximately 11 mm (from 12 to 6 o'clock); it is mostly flat with a plaque-like low papule off center to the lower right. All of the borders are indistinct; the outline is quite irregular; the lesion is asymmetric; the colors vary from pink to light tan. The lesion is from an individual with quite fair skin and hair who does not make dark pigment. There are also two small other nevi in the photo with the same range of pigmentation.

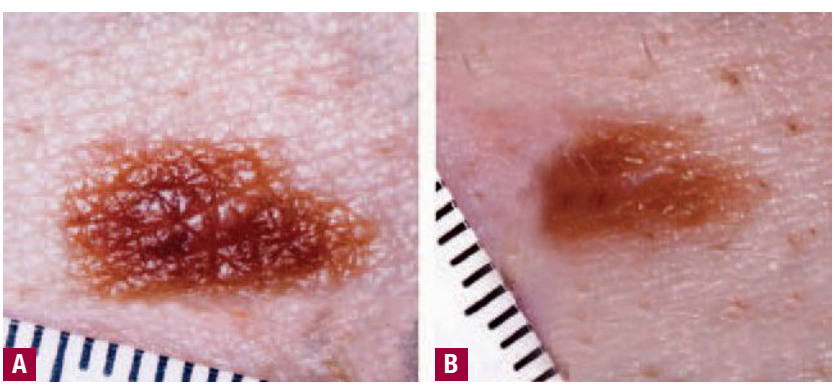


▲ **FIGURE 123-8** This lesion is 7 mm in greatest diameter and predominantly flat. It is quite irregular in outline and asymmetric. The borders are somewhat smudged in some areas; there is clear pigment variation. This person makes very dark nevi; this lesion was typical of many of the patient's nevi.

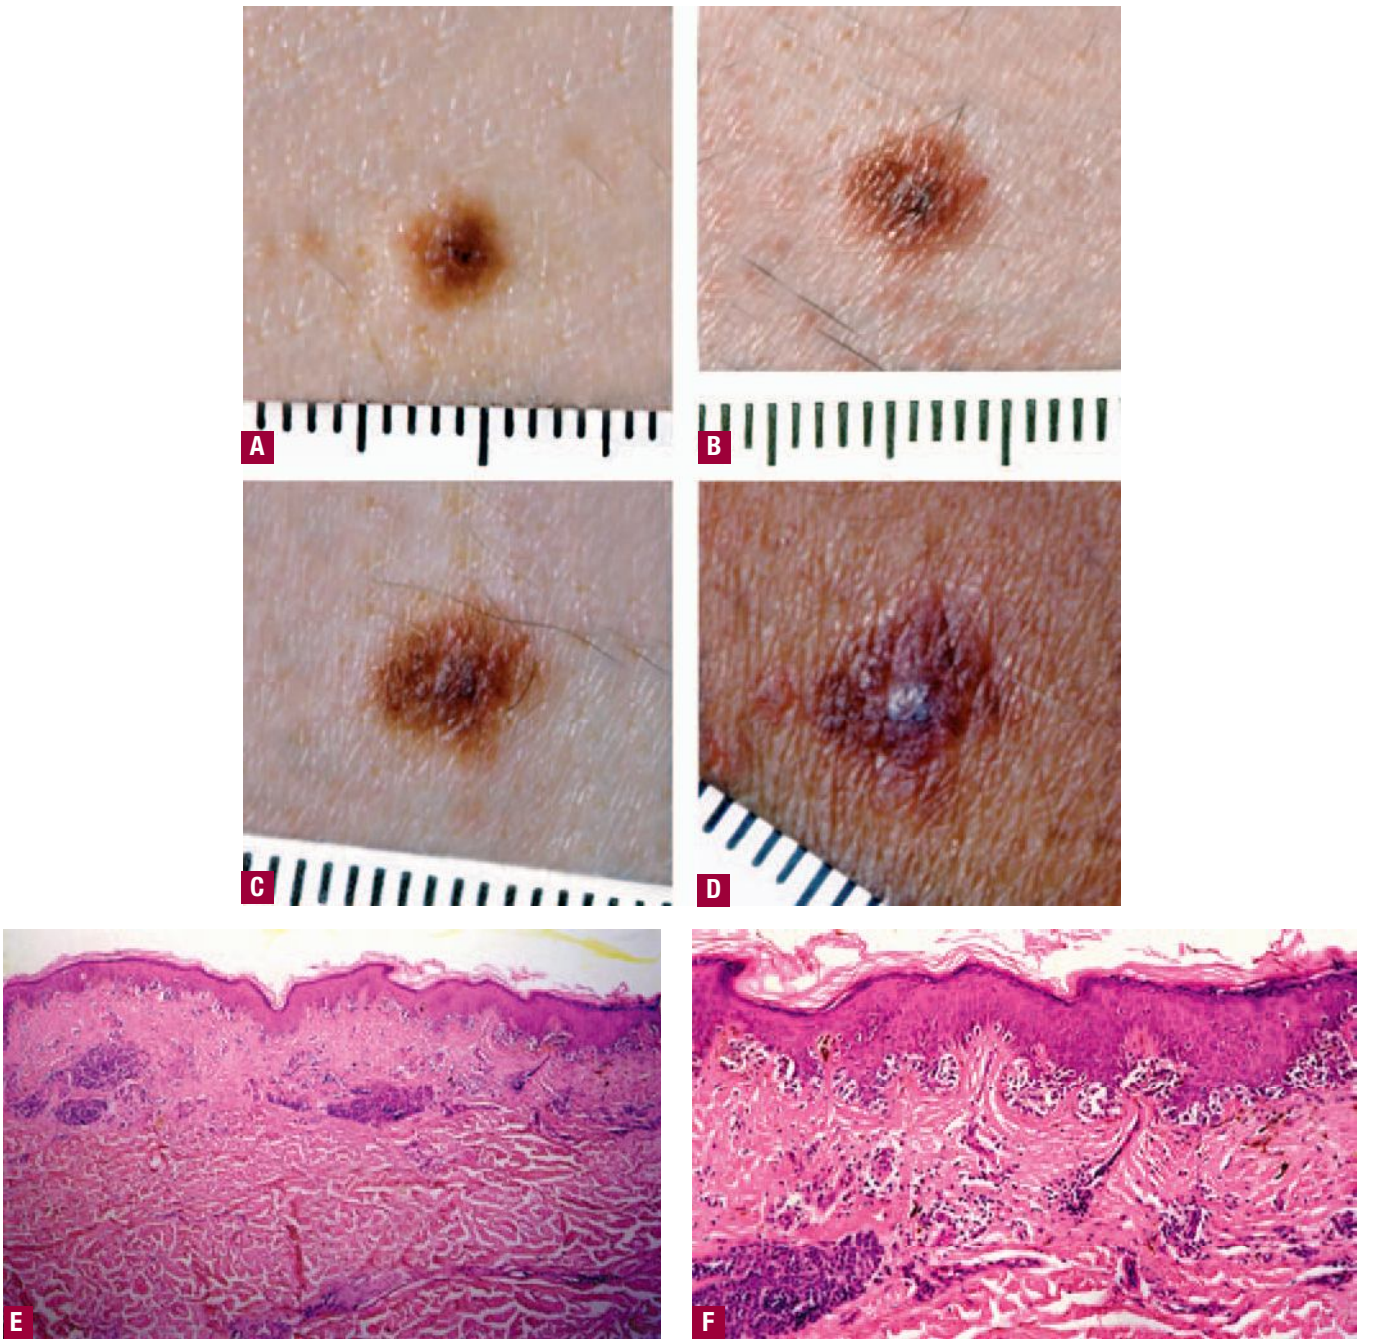
see Fig. 123-1). If a lesion is completely raised or papular, it is not a DN. Many DN, in the process of involution, become fully papular, and are no longer considered dysplastic. The surface of a DN usually retains fairly normal skin markings (Fig. 123-7A). If there is a papule without skin markings, one needs to think about an expansive process that distorts the architecture, such as a growing tumor. The lesions are asymmetric with an irregular outline. Often the outline is "geographic" and quite irregular. Lesions are frequently rhomboidal or polygonal; others may be almost ovoid or round, but have irregular projections into the surrounding skin (Fig. 123-8). The borders of the lesions are often smudged, with the pigment fading into the adjacent skin. Some of the border may be definitive; other areas may be indistinct. Color variation usually ranges from pink to very dark brown, but this needs to be evaluated in comparison with other pigmented lesions an individual has (see Fig. 123-3B). A very dark brown area in someone with a fair complexion may be suspicious for melanoma. Conversely, someone who is quite dark may make very dark nevi. A prominent erythematous component may correspond to an inflammatory infiltrate in the lesion. A disproportionate erythema in lesion in comparison with other lesions may also be suspicious for melanoma. Similarly, an area of central inflammation and pigment clearing in a DN may be suspicious for regressing melanoma.

Most DN start as ordinary appearing small, symmetric nevi (Fig 123-9A).[47] Unlike other nevi, they continue to enlarge in diameter over varying periods of time. Often, one of the first atypical

▲ **FIGURE 123-6** This lesion is 11 mm in diameter, with a "pebbly" central papular area and a several mm "shoulder" around the papular area. The borders are irregular and quite indistinct around the whole lesion. There is color variation from pinkish tan to medium brown.



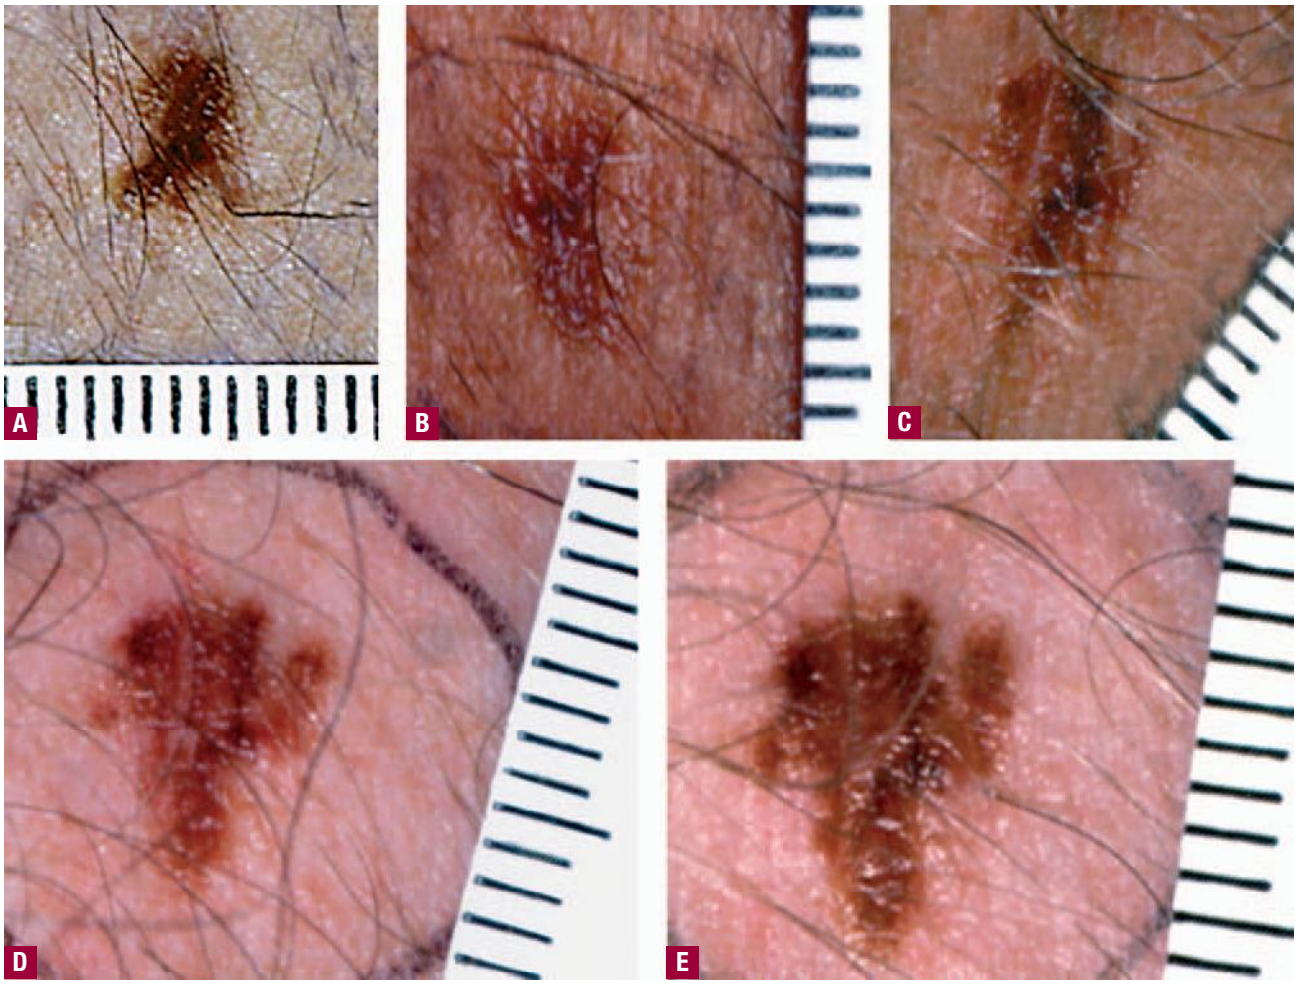
▲ **FIGURE 123-7** **A.** This is a lesion with largest diameter 8 mm, primarily flat with a central low papule, irregular outline, somewhat indistinct border at the upper left corner and far right protrusion, and variable pigmentation. The normal skin markings are well seen. **B.** The same lesion 4 years later after initiation of rigorous sun protection. The entire lesion is flatter. On the right side of the lesion in the area of the "shoulder," there is clear involution of the promontory and invagination of the shoulder area just above it. On the left, the outline has also invaginated toward the center. The entire lesion is also substantially lighter. This is an involuting dysplastic nevus.



▲ **FIGURE 123-9** **A.** A close-up was taken of this lesion because of increasing prominence in comparison with previous overview photographs. The lesion does not meet criteria for a clinical dysplastic nevus (DN). The largest diameter is not over 5 mm, but it is somewhat irregular in outline with indistinct borders and variable pigmentation. **B.** The same lesion 2 years later has increased in size to 6 mm; become more irregular with an indistinct border from approximately 4 to 6 o'clock and from 11 to 1 o'clock. The central hyperpigmentation has increased, and there is the beginning of central elevation. The lesion now meets criteria for a DN, but is not suspicious for melanoma. **C.** A year and a half later, the lesion now measures 7 mm and has become more irregular and asymmetric. The central papule is dark, but consistent with many other nevi. **D.** A year later, the patient had been using a sunbed for several months and was deeply tanned. The borders of the lesion are difficult to appreciate; the surface of the central papule is exfoliative and has lost the skin markings. The lesion was removed because of the continued changes. **E.**, **F.** There is a plaque of nevus cells at the base of the photomicrograph. Above this, there is an increased amount of connective tissue. Along the dermal-epidermal interface, there is proliferation of moderately atypical melanocytes. Below them is concentric eosinophilic fibroplasia. (Photomicrographs used with permission from Wallace H. Clark, Jr.)

features is a smudging of the border of the lesion, followed by increasing irregularity of outline, and increasing asymmetry (see Fig. 123-9 B,C). Color variation may appear early. Some lesions will have growth arrest before reaching a diameter of 5 mm. Often the nevi will remain as relatively flat lesions over extended periods of time. Some will develop a central papule and evolve to a more typical compound or dermal nevus. As this occurs, the flat component generally recedes toward the papular component (see Fig. 123-7 A,B). Over time, most lesions involute and disappear, leaving no obvious trace.[47]

The most important clinical question in following each specific nevus is the determination of whether or not it is a melanoma (see Chap. 124). When using the "ABCDE" criteria in assessing a DN, each



▲ **FIGURE 123-10** The lesion's histopathology is demonstrated in Figure 123-2. **A.** The lesion was photographed because of increasing prominence on overview photographs. It meets all the clinical criteria for dysplastic nevus: It is larger in diameter than 5 mm; is asymmetric with irregular, indistinct borders; and has variable pigmentation. **B.** Four months later, after a couple months of sunbed use,[119] the lesion is somewhat darker, but it is difficult to see distinct boarders because of the deep tan. The outline generally looks similar to the previous photo. **C.** A year later, after continued sunbed use, the lesion is larger, darker, and more asymmetric. It had changed less than other lesions, and other, higher risk lesions were removed. **D.** Six months later, after stopping tanning, the lesion is much lighter. The darkest areas have lightened considerably. The upper pole of the lesion is expanding, and the whole lesion is asymmetric with some indistinct borders. **E.** Three months later, the darker areas were even darker and larger, and the lesion was excised. (Photomicrographs used with permission from Wallace H. Clark, Jr.)

characteristic will be a matter of degree, because DN share these characteristics with early melanoma (Asymmetry, Border irregularity, Color variegation, Diameter greater than 6 mm, and Evolving over time).[55–57] When assessing the evolution, change towards senescence or involution is not worrisome, but change towards morphology closer to melanoma is. Continuing change over several examinations out of proportion to changes in other lesions is also of concern for melanoma (Fig. 123-10).[47] Each lesion should be assessed within the context of the other lesions an individual has. For instance, a lesion on someone with red hair that has a quite dark brown area may be more suspicious for melanoma (because that individual doesn't usually make dark brown pigment) than a lesion with almost black pigmentation in a darker skinned individual. Some individuals have multiple lesions with severely atypical morphology, but the lesions have not changed over years.[47] These lesions usually do not need to be biopsied. If most lesions, including other DN, are in the process of involution, but a DN remains stably atypical or progresses and becomes even slightly more abnormal appearing, then it is reasonable to biopsy the lesion. Obviously, a new dark area in a previously relatively stable lesion is suspicious for melanoma. One becomes most suspicious of a lesion if it is disproportionately more atypical appearing than all of the other lesions. A recent survey of dermatologists[58] in Europe suggests that most dermatologists already use such a process. The recognition of melanoma is more of an overall pattern recognition and a differential recognition process, also known as the "ugly duckling sign," than an analytic criteria recognition (systematically going through all of the ABCDE criteria). The best predictors of melanoma were overall irregularity, the ugly duckling sign, and history of recent change.

Earlier recommendations suggested biopsy of a suspected DN at the time of initial examination to verify histologically that an individual has DN.[60] Over time, with the validation of epidemiologic studies identifying the clinically diagnosed DN as risk markers of melanoma and with the established reproducibility of the clinical diagnosis, it has become clear that the clinical diagnosis can generally be used for patient management. Many individuals with multiple DN will likely have excisional biopsy of lesions at some time in their clinical course; histologic information can be obtained at that time. This approach is also consistent with the rec-

ommendation that the only reason to biopsy a DN is to rule out melanoma.

Related Physical Findings

The major related physical findings in an individual with DN are the cutaneous phenotype and extent of solar injury, both of which are independent risk factors for melanoma.[54] Individuals who are heavily freckled and have DN are at higher risk of developing melanoma than those with DN who are not freckled.[9] In the nonfamilial setting, these effects appear additive. Recent melanoma studies have evaluated the variations in *MC1R*, the melanocortin 1 receptor gene, as a risk factor for melanoma.[61–65] Some variations in the gene are related to the freckling phenotype, fair skin, and red hair, the "red hair variants." Other, more common variants do not have a recognizable phenotype, but do increase melanoma risk. In melanoma-prone families, many individuals have information not only on the cutaneous phenotype, but on genetic variations in *MC1R* as well as the major melanoma susceptibility genes.[66–69] All the family studies showed an increase in risk of melanoma in *CDKN2A* mutation carriers associated with *MC1R* polymorphisms. Multiple alleles raised the risk higher. Only one study also evaluated DN. Within these families, DN and variations in *MC1R* both increase the risk of melanoma in *CDKN2A* mutation carriers.[69]

Evidence of chronic solar injury is also associated with an increased risk of melanoma in men with DN, especially in older men.[54]

Laboratory Tests

HISTOPATHOLOGY The major relevant diagnostic laboratory tests are the careful histologic examination of excised lesions. It is helpful to alert the pathologist to the particular area of concern that led to the biopsy. Sectioning through the area of most interest is essential to ensure that melanoma is not missed. The pathologist should also comment on the adequacy of the excision margins.

Histopathologic features are an immature growth pattern and random cytologic atypical of melanocytes (see Fig. 123-2) and a lymphocytic host response.

DN occupy a middle ground between common acquired nevi and early melanoma. As with virtually any biologic phenomenon, there is a continuum in melanocytic lesions between completely banal and malignancy. The difficulties in clinical and histologic diagnoses of DN lie in the border between common acquired nevi and nevi that barely meet criteria for DN (see Fig. 123-9E); and between severely DN and early melanoma (see eFig. 123-10.1 in on-line edition; see Figs. 123-2, 123-10F). The newly described *de novo intraepidermal epithelioid melanocytic dysplasia* is a variant that may lie within the severely DN-melanoma in situ continuum.[70]

The histologic diagnosis of DN can be considered in two components: architectural and cytologic.[71] The lesions are usually larger than common nevi; interpreting small lesions may be problematic. There is usually a junctional component which may be most of the lesion, or an edge or shoulder to a compound papule. The junctional component extends several retia beyond the dermal component. In the lesion, particularly in the junctional component, melanocytes are frequent, either singly or usually in small nests. Rete ridges are elongated, with the nests of melanocytes along the side or at the tips. Occasionally, the nests bridge between retia. There is fibroplasia in the dermis, often concentric eosinophilic fibroplasia or lamellar fibroplasia. Lymphocytes tend to be patchy and perivascular. Scattered melanocytes along the dermal-epidermal junction (at least 5 to 10) are atypical (random cytologic atypia). The atypical melanocytes are one-third to one-half larger than the melanocytes in the normal surrounding skin and have more abundant cytoplasm.[72] The nuclei of the normal melanocytes tend to be 4 to 6 μm, but those of the atypical melanocytes are 8 to 24 μm. The nuclei may be slightly irregular or folded with hyperchromasia and clumping of chromatin. Some may have prominent nucleoli. The melanocytes in DN are intermediate between ordinary nevus cells and early melanoma with regard to histologic characteristics, cell surface markers, and (often) somatic mutation detection. Several groups have proposed criteria for grading histologic dysplasia to help place a specific DN within the spectrum from almost normal nevus to melanoma.[13,73–75] Most of these systems, when evaluated, have good intraobserver reproducibility, but less interobserver reliability. It is often helpful for the clinician, however, for the pathology report to include an assessment whether the lesion is close to melanoma, because those lesions may need re-excision.

SPECIAL TESTS For clinical care of individuals with DN, full body photography is an essential tool.[47] Both overview photographs and close-up photographs of the most atypical nevi are extremely useful. These may be difficult to obtain in a practice with limited access to photography. The quality of the photography often reflects the frequency with which patients having pigmented lesions are seen and photographed, not just the quality of the photography equipment. Several algorithms for "covering" full skin surface areas have emerged, each with some advantages. In evaluating the different algorithms, it is useful to note how well each displays the anatomic regions with sufficient magnification and illumination to evaluate patterns, relative sizes, and pigmentary characteristics of nevi. Another important consideration is how reproducible the system is within one's practice. The usual system chosen may have to be altered for individuals with profuse dark body hair because the pattern and size of nevi with standard overviews may not be visible. The important uses of overviews in future examinations include (1) recognition of new lesions; (2) change in specific lesions in relation to others (see eFig. 123-10.2 in on-line edition); and (3) involution of lesions over time. There are commercially available photography management tools to aid in organizing the images for each patient. Each practitioner should evaluate what system works best in their practice and use this consistently.

Close-up photographs of the most atypical appearing nevi should be at 1:1 or 2:1 magnification with a ruler in the photograph (see Fig. 123-10). This allows careful comparison of the size, outline, color patterns, surface patterns, and skin markings at the time of the photograph with examinations in the future. In addition, photography of scalp nevi is also useful when they are not visible on overview photos. The location of each close-up photograph should be recorded to aid in identifying the specific nevus at future examinations. Again, commercially available management tools may be helpful. Many studies have demonstrated that the comparison of previous photography with the current skin examination aids in the recognition of changing lesions. Melanomas occurring in patients who are regularly followed using clinical photographs appear to be predominantly in situ or very thin invasive melanomas.[47,76–82]

In experienced hands, dermoscopy, or epiluminescence microscopy, is also a useful adjunct for examining specific lesions. Dermoscopy is a skill acquired through formal training, and it requires proficient pattern recognition and analy-

sis. It is more widely used and taught in Europe than in the United States. It is often impractical to examine every DN with dermoscopy during a routine evaluation, especially of someone with many DN. Most practitioners use dermoscopy only to examine select lesions.[82] Recent atlases have illustrated dermoscopy of DN and melanoma.[83,84] Several sets of criteria for differentiating nevi, including DN from melanoma, have been developed, including pattern analysis, ABCD (Asymmetry, Border, Color, Dermascopic structures) rule, Menzies method, and 7-point check list. These algorithms were compared among expert examiners.[85] Pattern analysis was the preferred method among most participants. It is not surprising, therefore, that the interobserver agreement was good for this method and that this method performed best, with highest sensitivity and specificity. There was substantial interobserver variation among the different variables in sets of criteria, but very high intraobserver consistency. This implies that the observers may interpret the components of the criteria differently but were very consistent in their interpretations. This analysis, however, did not focus specifically on DN.

Digital epiluminescence microscopy (digital dermoscopy) is also available, in which the digital dermoscopy images of specific pigmented lesions are stored and compared. Dermoscopic imaging in follow-up surveillance can thus be captured, similar to sequential photography of pigmented lesions. Sequential digital dermoscopy in compliant patients by experienced examiners increased the specificity of diagnoses.[90] Multiple different systems are available[86,90–92]; there are sparse data on direct comparisons between the systems. Some of the systems also include image analysis for automating diagnoses. Evaluation of the diagnostic precision of both dermoscopy by clinicians and digital dermoscopy with image analysis suggests that some systems may perform as well as or better than clinicians.[93] There is some evidence that these more quantitative comparisons may lead to higher specificity in the recognition of early melanoma. There is still major overlap, however, between DN and early melanoma.[94] Use of digital dermoscopy may also enhance confidence in care provided and an enhancement of self skin exams.[95] Use of digital epiluminescence microscopy is time consuming for the patients and the staff. The costs of the equipment at this time would likely limit the use of the modality to clinics having a high number of patients with pigmented lesions being followed.

New imaging techniques, such as confocal scanning laser microscopy, also hold much promise for identifying very early melanomas.[96,97] Confocal microscopy can visualize tissue architecture down to the papillary dermis at the individual cell level. Criteria for the diagnosis of melanoma are being developed. Specific criteria for DN should follow. Again, the technology is expensive, and the imaging is time consuming.

Box 123-1

Differential Diagnosis

Most Likely

- Common acquired nevus
- Congenital or congenital-type nevus
- Dermatofibroma
- Seborrheic keratosis

Consider

- Combined nevus
- Spitz nevus/Spitz variant
- Pigmented spindle cell nevus
- Blue nevus
- Pigmented actinic keratosis

Always Rule Out

- Melanoma in situ
- Superficial spreading melanoma
- Pigmented basal cell carcinoma

Differential Diagnosis (Box 123-1)

COMPLICATIONS

The major complication of DN is melanoma, but melanoma is a relatively uncommon event. These lesions are both risk markers for melanoma and precursor lesions for melanoma. Numerous studies have documented that DN are dynamic lesions, but only a small percentage progress toward or develop into melanoma.[79,82,89]

In most of the case-control studies evaluating risk of melanoma, the risk increases with more DN.[9,15,98,99] These risks are estimated based on the clinical recognition of DN. At this time, there are few data to address the risk of melanoma associated with only histologic evidence of DN. The correlation between the clinical and histologic diagnoses is not perfect; the optimal evaluation of this has not yet been done. It is likely that some of the discrepancies between histology and clinical diagnoses are in the border between normal and minimally dysplastic and between severely dysplastic and melanoma.

A continuum of risk of melanoma from the border of common acquired nevi to mild dysplasia to severe dysplasia is likely. In one large study, there was no risk associated with clinically very mild lesions that were at the borderline between normal and dysplastic where experienced observers disagreed about the diagnosis.[15] One unequivocal DN, however, increased risk of melanoma twofold. More than 10 increased the risk 12-fold [95 percent confidence interval (CI): 4.4–31]. A meta-analysis of 47 studies revealed the risk of melanoma associated with any atypical nevus was 10-fold increased (95 percent CI: 5.0–20.3).[99] The different studies used various criteria for the classification of a nevus as atypical or dysplastic. There was evidence of heterogeneity of the risks associated with DN according to the type of study (case-control vs. cohort), source of controls (hospital, population, or other), and exposure measure (dichotomous or not). Some of the heterogeneity in the combined data likely reflects the different diagnostic criteria for DN in the studies. When the analysis was limited to case-control studies, the risk of melanoma associated with five or more DN was sixfold increased (95 percent CI 3.8–10.3). Individuals with DN and melanoma are more likely to develop multiple primary melanomas than individuals who have melanoma, but not DN.[53] Individuals who are immunosuppressed, such as those with transplants[100,101] or those who have had lymphoma,[102] are at two- to eightfold more likely to develop melanoma. Where it has been investigated, the melanomas occur in individuals with DN.

Removal of all DN is not recommended for several reasons. Complete removal of all DN is not only unnecessary surgery; it also does not alter the need for continued surveillance of these individuals. Individuals with DN continue to develop new nevi until late middle age, and can develop melanoma de novo not associated with a nevus.[47] Some have hundreds of nevi, tens of which are dysplastic. Most nevi will undergo physiologic involution. Removal of all of the nevi does not change the need for careful sun protection, regular skin self exams, or routine professional examinations. Nevi need only be removed when clinically suspicious for melanoma.

PROGNOSIS AND CLINICAL COURSE

Much of the natural history information about DN derives from longitudinal studies of melanoma-prone families.[47] In

these families, DN may start to appear early in childhood. For some reason, atypical lesions may first appear on the scalp of young children, not usually in infancy or in toddlers.[103] For most children in melanoma-prone families who go on to develop DN, the first finding is an increased number of small typical nevi, most often in sun-exposed areas (see Fig. 123-10A).[104] Over time, some of these lesions grow in diameter, become more asymmetric with irregular, indistinct borders and variable pigmentation (see Fig. 123-10 B,C). Often by the time of puberty, characteristic DN exist. During puberty, individuals often develop more nevi and more atypical nevi. Children who have been carefully sun-protected tend to develop many fewer nevi. These findings are consistent with the epidemiologic studies which have shown that sun protection decreases the number of nevi that develop in children from the general population.[105]

Typically, DN are most frequent on intermittently exposed skin surfaces.[44–47] Epidemiologic studies have demonstrated that the most frequent site is the back; often the large irregular nevi are prominent on the lower back (see Fig. 123-3A), with relative sparing of the heavily sun-exposed upper back and shoulders. DN can, however, occur in minimally sun-exposed areas such as the doubly covered buttocks, breasts, scalp, and pubic regions. Individuals with DN may also develop nevi, not necessarily atypical, on palmar and plantar surfaces and in webspaces of hands and feet. It is uncommon for individuals with DN to have nevi on mucosal surfaces, but they do occur.

Individuals with DN continue to develop new nevi late into adulthood.[79,82,89] The majority of nevi in individuals with DN are ordinary common acquired nevi. In a longitudinal study (at least 5 years of follow-up) of individuals with DN in a pigmented lesion clinic, nevi were dynamic lesions.[79] One-third of individuals developed new nevi; most new nevi occurred in individuals under age 30. About one-half of the lesions with close-up photographs changed over time; 15 percent of lesions developed more atypical features; 35 percent became less atypical. Among these nevi, 2.4 percent disappeared. During the study period, 11 of 153 individuals developed new melanomas 0.25 to 0.85 mm thick. In a prospective study from Australia, nevi were also dynamic, but the study did not give specific information on DN, and the rates of change were highest in the individuals with over 20 DN at the first visit.[89]

Relatively few of an individual's total nevi are dysplastic (see Figs. 123-3A, 123-10C). Even in individuals from melanoma-prone families, the majority of DN involute and disappear over time.[47] Nevi and DN tend to have periods of relative stability and periods of increased activity, when several new nevi appear and existing nevi change in color, size, or appearance. The triggers for this activity are not well studied; anecdotally, sun exposure seems to stimulate nevus activity (see Figs. 123-9, 123-10, see eFig. 123-10.1 in on-line edition). After sun or UV exposure, new nevi may appear and existing nevi may enlarge, become more irregular, or darken. Pregnancy also seems to increase the number, size, and sometimes, pigmentation in DN. Long-term prospective studies documenting total changes in all nevi over decades (appearance, development, changes, involution) have not been done. The relationship of activity of nevi to molecular markers of senescence also has not been explored. Changes in tissue microenvironment or signaling may also be important in nevus changes.

Nevus counts and counts of DN in general decrease with age. In a longitudinal study of Australian individuals at increased risk of melanoma,[89] those over age 50 had fewer nevi develop or change. If lesions changed, however, they were more likely to be melanoma. Over age 50, most individuals do not have clinical DN.[15] Those who have remaining DN are at highly increased risk of melanoma. The lack of normal involution of these lesions may be a powerful risk marker for melanoma. About 20 percent of individuals who have had DN in their forties, though, continue to develop new nevi beyond age 50,[79] again indicating that they may have an "activated melanocyte system."[106]

The risk of melanoma has also been estimated among individuals with DN who have been followed in pigmented lesion clinics for a number of years.[79,82,89,107] In general, these patients were followed at least yearly. Overview and close-up photographs were used, and dermoscopy of suspicious lesions was also often used. Although the measures of level of risk of melanoma vary between studies, in general, the risk associated with the presence of DN was substantially elevated overall and increased with more DN. The risks tend to be highest in individuals with a personal and family history of melanoma; followed by those with a family history of melanoma, but no personal history; then those with a personal but no family history of melanoma; and lowest in those with neither personal nor family history of melanoma.

Although the familiarity of DN is not fully understood, it is reasonable to examine the first-degree relatives of individuals with multiple DN. If they are found to have DN, the same approach should be followed for their care.

The recommended frequency of regular health care provider examinations has not been systematically evaluated. Empiric recommendations have been suggested for individuals in melanoma-prone families,[47,108] but these have not been rigorously evaluated in a prospective study. The risk in these individuals is also likely to be higher than in individuals with DN without a family history of melanoma. For individuals having a large number of severe DN, it is reasonable to begin following them at 3-month intervals. If their nevi are relatively stable, this time can be extended to every 6 months, then to yearly. If an individual has few mild DN, yearly exams are reasonable. Whenever the activity of the nevi increases, new nevi are developing, and/or nevi are becoming darker and more irregular; it is important to increase the frequency of exams. The frequency of exams is also an interplay between what the individual patient will tolerate (with work absences, care expenses, etc.) and their reliability in performing skin self exams. If they are consistent in performing exams, and call for appointments when nevi are changing, the frequency of prescheduled exams can be more flexible.

Patients should receive copies of their overview and close-up clinical photographs for their use at home. A diagram of the close-up photos is helpful, especially for individuals with a large number of photographs. Patients should also undergo detailed instruction in skin self-examination using their photographs. The best methods for teaching the components of skin self-examination have not been systematically evaluated. Recent work has demonstrated that nurse instruction in skin self-examination using the patient's own photographs resulted in much better adherence to a program of regular self-exams.[109] There is also recent evidence that having patients map their moles on a body diagram may help improve self-exam accuracy.[110] The instruction about self-exams is also a good opportunity for reinforcing sun protective measures and the early recognition of melanoma. The determinants of continuing self-exams are not fully understood; women, highly educated individuals, people who have had skin cancers, and those who are confident about doing self-exams are more likely to do the exams.[111]

Education about sun protection is another component of the patient management. Although randomized clinical trial data are not available, a growing body of evidence supports the assumption that minimizing sun and UV exposure is prudent in individuals with multiple DN (see eFig. 123-10.1 in on-line edition). DN are both precursor lesions and risk markers for melanoma.[59] Minimizing exposure to the major environmental risk factor for melanoma, UV exposure, is warranted in this group. The suggestions for sun protection should be the same as those for the prevention of melanoma: avoidance of midday sun exposure, shade-seeking when out of doors, scheduling outdoor activity for early morning or late afternoon, use of protective clothing, and use of sunscreens. One of the important cohort studies that clearly established a risk of melanoma associated with use of UV tanning devices also demonstrated a high risk of melanoma in the women with large irregular nevi on their legs (14 percent of the cohort overall; 27 percent of cases).[112] Unfortunately, the authors did not report whether those with irregular nevi had a higher risk associated with using the tanning devices than those without the irregular nevi. Nonetheless, it seems sensible to advise that individuals with DN not use tanning devices.

Although there have been some reports of individuals with ocular melanoma being more likely to have DN, it is likely to be an extremely rare event. In a survey of usual practices among dermatologists, only 2.9 percent always recommended an exam for ocular melanocytic neoplasms.[113] Another 11.5 percent said they usually did. Most said that they recommended such an exam infrequently or never. It is reasonable to suggest that at the patient's next routine eye exam, they inform the ophthalmologist that they have DN. The ophthalmologist can, at that time, be alert for ocular pigmented lesions.

TREATMENT

Treatment of a DN that is suspicious for early melanoma is excisional biopsy of the entire lesion with visibly clear margins. Shave biopsies of these lesions are discouraged. Not infrequently, a shave biopsy does not fully excise the elongated rete, and the abnormal nests at the base of the rete are not removed. Repigmentation and re-growth can occur (see eFig. 123-10.1 in on-line edition). In melanoma-prone families, recurrences after shaves have sometimes been melanoma. The atypia in the melanocytes and nests is not uniform across the lesions. Because the major reason for removal of an DN is to rule out melanoma, it is important to completely remove the lesion to allow adequate histologic assessment of the lesion and the margins. One of the reasons commonly given for a shave biopsy is that the scarring will be less noticeable. If the shave is sufficiently deep to ensure removal of the entire lesion and to preserve the architecture for adequate histologic review, the scar will likely not be less noticeable. Because individuals with multiple DN may have a number of lesions removed over their lifetime, excisional biopsy with sutures may yield a much better cosmetic result for them. If the histology reveals severe dysplasia, reexcision to obtain adequate margins (usually 5 mm for severe dysplasia) may be required. In a survey of management of DN among dermatologists in practice that was conducted a number of years ago, 23 percent usually shaved a DN to fully remove it; 32 percent used saucerization, 12 percent used a punch, and 30 percent excised the lesion.[113]

Over the years, a number of different topical and systemic treatments have been tried to induce DN to differentiate or to remove them. One of the first agents was topical 5-fluorouracil (5 percent). Use of this agent on selected DN-induced inflammation, ulceration, and disappearance of the DN.[114] Parallel evaluations of topical and systemic antioxidants were then initiated. In a pilot study, topical retinoic acid–induced inflammation and clinical and histologic reversion toward common nevi.[115] Use of this agent, however, was limited by poor compliance due to skin irritation and inflammation. Another variation was adding cortisone to the treatment and using occlusive dressings.[116] A small randomized trial of oral β-carotene versus placebo for 3 years was conducted in 62 patients with numerous DN.[117] The endpoint was the number of new nevi that developed. At the time of analysis, there was no difference in the number of new nevi in the two groups. More recently, topical imiquimod cream (5 percent) was used three times a week for 20 weeks.[118] The endpoint was clinical response assessed by sequential confocal microscopy. There were difficulties in the comparison of the imaging techniques, but there were no obvious clinical changes in the treated lesions. The treated lesions showed a relative reduction of junctional and intraepidermal nevocytes with papillary fibrosis and some inflammation. The authors concluded that topical immune modulators may have some promise in chemoprevention of melanoma, but imiquimod did not warrant further investigation. In summary, although several promising topical agents have been tried, none have been efficacious and acceptable. These trials are difficult to design and conduct; there is a parallel large effect of removing UV exposure that affects the nevi and drives them toward regression/senescence. Documenting additional involution of nevi related to a medication can be problematic.

PREVENTION

The major preventive intervention for the development of dysplastic, as well as common acquired nevi, is likely decreased UV exposure, although this is not proven. With the growing body of evidence that childhood sun exposure is important in the number of nevi that develop,[105] it is important to initiate sun-protective behaviors early.

EPIDEMIOLOGY

The incidence of melanoma has increased significantly worldwide over the last several decades. In the United States, the lifetime risk of developing invasive melanoma was 1 in 1500 for persons born in 1935, 1 in 600 persons for those born in 1960, 1 in 150 persons for those born in 1980, and is estimated to be 1 in 62 persons for persons born in 2006 (1 in 34 including in situ melanoma). The American Cancer Society estimates that in 2006, 111,900 new cases of melanoma were diagnosed, including 49,710 in situ and 62,190 invasive cases (34,260 men and 27,930 women).[1] Melanoma had the greatest annual percent change in cancer incidence rate among the top 10 cancer sites by gender, all ages, and all races, between 1990 and 1997.[2] Invasive melanoma of the skin is the fifth most frequent site for cancer to occur in men and the sixth most frequent site in women, representing approximately 5 percent of all newly diagnosed cancers. Melanoma represents the most common cancer type in Caucasian women 25 to 29 years, second to thyroid cancer in women 15 to 24 years of age, and second to breast cancer in women 25 to 44.[3]

Mortality rates have also risen over the last several decades but not as quickly as incidence rates. The American Cancer Society estimates that in 2006, there were 7910 deaths (5020 men and 2890 women) due to melanoma.[4] Melanoma accounts for 79 percent of all skin cancer deaths. One American dies from melanoma approximately every hour. Melanoma is one of the leading cancers in terms of average years of life lost per death from disease. Although mortality rates have increased, survival for those diagnosed with melanoma have also increased. Based on U.S. Surveillance, Epidemiology, and End Results Program (SEER) data, the overall survival rates for melanoma were estimated at 60 percent in 1960 to 1963, 80 percent in 1974 to 1976, and 89 percent in 1992 to 1997.[5]

The mean age of diagnosis is relatively young at 52 years, which is 10 to 15 years earlier than the mean age of diagnosis in the more common tumors of the breast, lung, colon, and prostate. More than 25 percent of melanomas occur in persons less than 45 years of age. Incidence rises with age, especially in men. In the United States, women have a slightly higher incidence of melanoma before the age of 40 years. After age 40, men have a higher incidence, and the difference becomes remarkably large with increasing age. Mortality data parallel incidence data, with older men having the highest mortality rates. Although mortality rates in older persons, especially men, are rising, rates in younger persons and females have been steady or actually declined.[6] Lightly pigmented Caucasians have the highest incidence rates, much more than Hispanics, Asians, and African Americans.

ETIOLOGY AND PATHOGENESIS

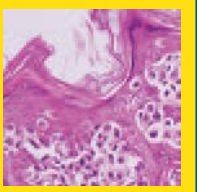
Risk Factors (Table 124-1)

SUN EXPOSURE Both genetic and environmental factors are related to melanoma pathogenesis and certainly not all melanomas are sun related. There is, however, clear convincing evidence that sun exposure, and more specifically ultraviolet (UV) exposure, is a major environmental cause of melanoma, especially in high-risk populations. Epidemiologic studies suggest that periodic, intense sun exposure (particularly during the critical time period of childhood and adolescence) rather than long, continued, heavy sun exposure is most important in melanoma causation, termed the *intermittent exposure* hypothesis. Sunburn history, notably blistering and peeling burns, serves as a surrogate measure of intermittent intense sun exposure. In one review of published literature, there was a significant positive association between sunburns during childhood and risk of melanoma development.[7] One blistering sunburn in childhood more than doubles a person's chances of developing melanoma later in life. Sunburns in adulthood have also been shown to contribute to melanoma risk.[8] Data from the behavior risk factor surveillance system of the Centers for Disease Control and Prevention show that nearly 32 percent of all adults aged ≥ 18 years, 58 percent between 18 and 29 years of age, and more than 40 percent of children report having had at least one annual sunburn defined as red skin for more than 12 hours.[9] Crude sunburn prevalence rates in white adults by state demonstrated higher sunburn rates among Caucasian adults living in the Midwest, possibly a reflection of a population that is more sun sensitive or less likely to practice sun-safe behaviors.

Migration studies generally indicate an increased melanoma risk in individuals who spent childhood in sunny geographic areas or emigrated to sunnier areas.[10] Younger migrants to sunny areas have an increased risk for melanoma as compared with adult immigrants. Lastly, there is an increased melanoma risk with longer duration of residence in the sunny locale.

Melanoma incidence and mortality among Caucasians correlate inversely with latitude of residence and dose of UV radiation, termed the *latitude gradient*.

MELANOMA AT A GLANCE



- Rising incidence worldwide; U.S. estimated lifetime risk of invasive melanoma is 1 in 1500 if born in 1935, 1 in 600 if born in 1960, 1 in 62 if born in 2006 (1 in 34 with inclusion of in situ melanoma).
- Risk factors: history of sunburns and/or heavy sun exposure, blue or green eyes, blonde or red hair, fair complexion, > 100 typical nevi, any atypical nevi, prior personal or family history of melanoma, *p16* mutation.
- Mean age of diagnosis: 52 years, 10 to 15 years younger than other more common cancers, (e.g., breast, lung, colon, and prostate).
- Most common location: back in men, lower extremities, then trunk in women.
- Features used for melanoma recognition: A (asymmetry), B (irregular borders), C (color variegation), D (diameter > 6 mm is most common use but others have changed D to difference-"ugly duckling" sign or different with respect to change in size, shape, color, or persistent lesional pruritus), E (evolving over time).
- Follows highly variable course and represents a heterogeneous disorder.
- Surgically curable if diagnosed and treated in early phase, but potentially lethal with increased risk when diagnosed and treated late.

TABLE 124-1
Risk Factors for Cutaneous Melanoma

- Ultraviolet radiation exposure
  - Blistering sunburns at any time in life; intermittent or sporadic high levels of exposure
  - Excessive chronic exposure to sunlight
- Phenotypic characteristics
  - Fair skin, inability to tan, tendency to sunburn or freckle (SPT I and II)
  - Blue or green eyes
  - Red or blond hair
  - Numerous typical nevi and/or more than one atypical nevus
  - Large congenital nevus
- History of prior melanoma
- Family history of melanoma
- Mutation in p16, BRAF, or MC1R
- Xeroderma pigmentosum
- Immune suppression (debatable)

The highest rates are nearest the equator. In areas as geographically diverse as the United States, New Zealand, and Australia, the incidence of melanoma is greater in regions closer to the equator. However, this gradient may be confounded by other risk factors for melanoma. In Italy, for example, more darkly pigmented persons reside in the South whereas more lightly pigmented persons live in the North, so that the latitude gradient is actually reversed.[3] Even in the United States, SEER data from 1992 to 2001 demonstrate that the latitude gradient applies only to non-Hispanic whites; melanoma incidence was not associated with latitude and UV index in African Americans, Hispanics, Asians, and Native Americans.[11]

The anatomic distribution of melanoma by body site demonstrates that intermittently exposed skin areas have the highest rates of developing melanoma. In men, the trunk, particularly the upper back, is the most common site for melanoma. In women, the lower legs, followed by the trunk, are the most common sites.[12] These intermittently exposed areas are the most common areas to develop melanoma in younger persons. In older persons, there is a greater incidence of melanomas located on chronically exposed areas with maximal cumulative sun exposure. The face is the most common location for melanoma in older persons, with the addition of the neck, scalp, and ears as well, in older men.[13,14]

Several forms of artificial light have been associated with the development of melanoma, particularly psoralen and ultraviolet A light (PUVA) and UVB, and tanning booths. The so-called *PUVA Follow-up Study* demonstrated increased rates of melanoma after PUVA exposure, with an incidence rate ratio of 9.3 approximately 20 years after PUVA therapy; these rates increased over time and were higher in patients exposed to high doses of PUVA.[15] However, the role of PUVA in the development of melanoma has been disputed (see Chap. 239). There is also rising concern over tanning beds and melanoma risk, especially as exposure to the artificial UV radiation is intermittent in nature. Any exposure to artificial tanning devices modestly, but significantly, increases the risk of cutaneous melanoma (odds ratio, 1.25), and longer duration of bed use, younger age at first exposure, and higher frequency of use are associated with a significantly elevated risk (odds ratio, 1.69).[16]

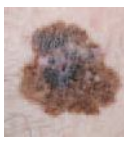
SKIN PHENOTYPE Light skin pigmentation, blond or red hair, blue or green eyes, prominent freckling tendency, and tendency to sunburn with Fitzpatrick skin phototype I–II are phenotypic features associated with an increased risk of melanoma. Melanoma occurs infrequently in type V–VI skin, suggesting that skin pigment plays a protective role.

MELANOCYTIC NEVI There is an increased risk of melanoma associated with nevi, both in a quantitative (i.e., number of nevi) and qualitative (i.e., typical vs. atypical nevi) manner. Adults with more than 100 clinically typical-appearing nevi, children with more than 50 typical-appearing nevi, and any patient with atypical nevi (see Chap. 123) are at risk. Tucker et al. found that the presence of a solitary dysplastic nevus doubled the risk of melanoma, while having 10 or more atypical nevi was associated with a 12-fold elevation of risk.[17] Nevi more often serve as a genetic marker of increased risk rather than a pre-malignant lesion, as most melanomas arise de novo. In a study of 1606 patients with melanoma, only 26 percent of the melanomas were histologically associated with nevi (43 percent of these atypical nevi, 57 percent other nevi).[18]

On the other hand, large congenital nevi are recognized potential precursors of melanoma, although the degree of risk varies depending on the size of the lesion (see Chap. 122).[19] Many series define large congenital nevi as greater than 20 cm in diameter in adulthood, and lifetime risks for developing melanoma are generally accepted to be in the 5 percent to 10 percent range. It is estimated that 70 percent of melanomas in large congenital nevi develop before the age of 10 years old and may occur deep within the nevus or even in the central nervous system, making detection of a thin lesion difficult. Patients with large congenital nevi located on the posterior axis (paraspinal, head, and neck regions) or in conjunction with multiple satellite lesions are at risk for neurocutaneous melanosis, with an increased risk of developing melanoma in the central nervous system. For small- to medium-sized congenital nevi, the melanoma risk is similar to any other area of skin; in this case, melanoma usually occurs later in life (after puberty), and arises at the dermal-epidermal junction, making early detection possible.[19] Thus, prophylactic excision of small- and medium-sized congenital nevi is usually unwarranted.

FAMILY HISTORY Patients with familial melanoma are estimated to account for 10 percent to 15 percent of all patients with melanoma. Having one first-degree relative with melanoma doubles the risk of melanoma, whereas having three or more first-degree relatives with melanoma increases the risk 35- to 70-fold.[20] Some of this risk may be attributed to shared risk factors such as skin phenotype, multiple nevi, and excessive sun exposure. The association between familial melanoma and multiple atypical nevi has historically been given various names, including *B-K mole syndrome*, *familial atypical multiple mole-melanoma syndrome*, and *dysplastic nevus syndrome* (see Chap. 123). Patients with familial melanoma typically have earlier onset melanoma and multiple primaries as well as atypical nevi. The molecular basis for some familial atypical multiple mole-melanoma syndrome kindreds will be discussed in Genetics.

PERSONAL HISTORY A previous history of melanoma increases the risk for another primary melanoma, with 5 percent to 15 percent of individuals developing multiple primary melanomas.[21,22] In patients with multiple primary melanomas, roughly one-half develop a second primary tumor in the same region of the body (i.e., trunk, extremity, head, and neck) and roughly one-half develop a second primary melanoma within the first year of initial diagnosis. However, subsequent primary melanomas may develop decades after diagnosis of the



initial lesion, stressing the need for long-term surveillance. Subsequent melanomas are thinner compared with the first melanoma in roughly 70 percent to 75 percent of cases.[21]

Immunosuppression has also been described as a risk factor for melanoma with a two- to fivefold increased incidence reported post-transplantation in a few studies.[3] The increased incidence of melanoma with immunosuppression, however, remains debatable. Finally, a history of actinic keratosis or non-melanoma skin cancer also confers a small increased risk of developing melanoma.

GENETICS ***CDKN2A-CDK4-TP53 Pathway.*** Germline mutations in the chromosome 9p21 tumor suppressor gene, cyclin-dependent kinase inhibitor 2A (*CDKN2A*), account for approximately 40 percent of hereditary melanoma cases (≥ 3 melanomas in one lineage) and confer a 76 percent chance of developing melanoma in the United States[23]; concordant with ambient rates, this risk is somewhat higher in Australia and lower in Europe. Individuals with germline *CDKN2A* mutations also exhibit a higher risk of pancreatic cancer; an estimated 15 percent of individuals with a mutant allele will develop pancreatic cancer in their lifetime.[24] Bona fide deleterious point mutations in *CDKN2A* are relatively uncommon in primary melanoma tumors although homozygous deletions of this gene may obscure the true rate of somatic loss in melanoma. *CDKN2A*, encodes two gene products: p16 (also known as *INK4a*, inhibitor of kinase 4a) and p^{14ARF} (alternative reading frame). p16 is a cell cycle regulator that binds and inhibits cyclin-dependent kinases CDK4 or CDK6, thereby inhibiting progression of cells through the G1 phase of the cell cycle. If p16 function is absent or inactivated by mutation, unrestrained CDK4 activity phosphorylates the retinoblastoma protein thereby releasing the transcription factor E2-F and inducing S-phase entry. This sequence culminates in enhanced cellular proliferation which, in the absence of checkpoint regulation, results in unrestrained growth and neoplasia.

The binding partner of the p16 protein is CDK4. Only a handful of families worldwide thus far have been reported to carry hereditary mutations in CDK4 while somatic mutations in this gene have also been detected in some melanoma cell lines. Functional studies suggest that mutations in CDK4 render the cyclin-dependent protein kinase resistant to p16 inhibition, resulting in a phenotype identical to that from p16 loss.

The p^{14ARF} protein from CDKN2A inhibits a cellular oncogene MDM2, which in turn accelerates the destruction of the p53 tumor suppressor gene.[25] Thus, complete loss of CDKN2A also leads to abrogation of p^{14ARF} and loss of p53 function. Thus, this single locus can impact both the retinoblastoma protein and p53 pathways and probably explains the low rate of direct *TP53* mutagenesis in melanoma.

RAS Signaling Pathway. Davies et al. first reported in 2002 a somatic mutation in the *BRAF* gene in 66 percent of melanomas.[26] B-raf is a serine/threonine kinase, which is a major player in the Ras-Raf-Mek-Erk mitogen-activated protein kinase (MAPK) signaling transduction pathway that regulates cell growth, proliferation, and differentiation in response to various growth factors, cytokines, and hormones. The stimuli activate the G-protein Ras by inducing the exchange of guanosine 5′-diphosphate for guanosine 5′-triphosphate, which then binds and activates Raf. Raf phosphorylates and activates Mek, which in turn phosphorylates MAPK (i.e., Erks). This signaling cascade serves to intracellularly amplify the extracellular signals mediated by growth factors. There are three functional Raf proteins in humans, A-raf, B-raf, and C-raf. B-raf has a much higher basal kinase activity than either A-raf or C-raf, and somatic mutations in B-raf occur with moderate to higher frequency in melanoma and colorectal, ovarian, and papillary thyroid carcinomas, implicating activating oncogenic mutations of B-raf as critical promoters of malignancy.[27]

BRAF mutations are significantly more common in melanomas occurring on skin subject to intermittent sun exposure, with 81 percent of melanomas on skin without chronic sun damage having *BRAF* or *NRAS* mutations.[28] On the other hand, the majority of melanomas from acral sites (palms, soles, subungual skin), mucosa, or chronically sun-damaged skin do not carry a mutation in either gene. There are also significant differences in the number of copies of genomic DNA in melanomas located in the various regions. Melanomas with wild-type *BRAF* or *RAS* frequently had increases in the number of copies of the genes for *CDK4* and *CCND1* (cyclin D1), two critical G1 cell cycle proteins and two genes that are transcriptionally induced by activated MAPK signaling.[28]

Mutations in *PTEN/MMAC1* tumor suppressor gene also lead to enhanced Ras pathway signaling.[29] This protein/lipid phosphatase downregulates signaling through the Akt arm of the Ras circuitry. When PTEN is inactivated, there is dysregulated Akt activity along with increased cellular survival.

Other Genes. **MICROPHTHALMIA.** Recently, somatic amplifications of the microphthalmia (*MITF*) gene in a subset of melanoma tumors were identified, and it was demonstrated that overexpression of *MITF*, in conjunction with ectopic expression of *BRAF*, resulted in melanocyte transformation.[30] The Mitf protein is a transcription factor that appears to be a master regulator of melanocyte differentiation, and amplification of this gene appears to contribute to a novel carcinogenic mechanism known as *lineage addiction*.

MELANOCORTIN-1-RECEPTOR. As mentioned above, red hair and sun sensitivity represent epidemiologically demonstrated risk factors for cutaneous melanoma. Recently, mutations in the melanocortin-1-receptor (*MC1R*) were shown to strongly contribute to the red hair/fair skin phenotype.[31] As such, germline mutations in the *MC1R* gene have also been shown to increase melanoma risk by approximately two- to fourfold in the general population[32]; it also confers risk for non-melanoma skin cancer. Because the prevalence of *MC1R* mutations is quite high in the white population, its attributable risk to melanoma is higher than the rarer high-risk *CDKN2A* mutations.

XERODERMA PIGMENTOSUM GENES. Xeroderma pigmentosum (XP) is a rare autosomal recessive genodermatosis comprised of at least seven complementation groups each defined by a separate gene. The XP genes are involved in excising DNA photoproducts in a reparative program termed *nucleotide excision repair*. Thus, heritable defects in these genes lead to increased mutagenesis and early carcinogenesis. Patients with XP harbor a 600- to 1000-fold increased risk for skin cancer, including cutaneous melanoma.

BREAST CANCER SUSCEPTIBILITY GENE. Carriers of the breast cancer susceptibility gene, *BRCA2*, appear to harbor an increased risk for melanoma (2.58-fold).[33] Although an interaction between breast cancer and melanoma risk has been suggested on epidemiologic

grounds, the genetic interaction between BRCA2 and melanoma risk remains to be fully determined.

Tumorigenesis and Tumor Progression

Five stages of malignant transformation and tumor progression in melanocytes have been suggested, based on clinical, histopathologic, immunopathologic, cytogenetic, and in vitro properties: (1) benign melanocytic nevi; (2) atypical nevi; (3) primary malignant melanoma, radial growth phase; (4) primary malignant melanoma, vertical growth phase; and (5) metastatic malignant melanoma. It is believed that with each successive step of tumorigenesis, a new clone of cells emerges with growth advantages over the surrounding tissue, resulting in "clonal expansion." It has been postulated that a critical step in tumor progression of melanoma may be the transition from radial to vertical growth phases. The radial growth phase consists of primarily intraepidermal proliferation of melanoma cells, but also invasion of the papillary dermis by small numbers of cells that have gained a growth advantage. These cells are thought to have the capacity for autonomous proliferation in this location, but not for aggregative growth. Radial growth phase cells are characterized by the presence of E-cadherin, an adhesion molecule that interacts with keratinocytes and impedes migration of the cells from their intraepidermal location[34] Melanomas in this phase are probably incapable of metastasis. The vertical growth phase is signaled by the property of aggregative growth, resulting in the formation of expansile nests or nodules of cells. Because the metastatic cascade comprises a complex range of numerous biochemical events, the vertical growth phase is likely an oversimplified correlate for the metastatic phenotype. Among other characteristics, vertical growth phase cells lose E-cadherin and express N-cadherin, a molecule that interacts with fibroblasts, macrophages and endothelial cells. This latter interaction may facilitate intravasation of the malignant cells.[34]

A discussion of tumorigenesis of melanoma must take into account several important clinical observations: (1) the association between precursor nevi and melanoma in approximately 30 percent of cases (an apparent absence of precursor nevi in 70 percent of melanoma); (2) the role of UV light in the pathogenesis of melanoma; (3) pigmentary phenotype of patients in whom melanoma develops; and (4) family history of melanoma and other genetic factors. When the above observations are considered in light of the multistep process of tumor progression of melanoma, at least two major pathways of tumorigenesis can be envisioned.

In the first pathway, melanomas, particularly superficial spreading melanomas (SSMs), at least in some cases, develop in association with melanocytic nevi. Nevi may represent the first stage of tumor progression of melanoma or an initiated clonal proliferation. The most likely initiating agent would be UV exposure, perhaps at an early age. There is epidemiologic evidence that sun exposure earlier in life may result in larger numbers of nevi. The number of precursor nevi may be important as greater numbers of initiated cells would increase the target population for another mutational event. As UV is believed to be a complete carcinogen, sunlight exposure, perhaps of intermittent nature, could lead to this second mutational event, resulting in tumor progression. A second pathway of melanoma development is exemplified by lentigo maligna melanoma (LMM). This form of melanoma results from cumulative sun exposure and a corresponding cumulative insult to the DNA of melanocytes on sun-exposed skin. The age-incidence rates show a steady increase with age, consistent with continuous exposure (initiation) to a carcinogenic agent such as UV light.

Curtin et al. compared genome-wide alterations in the number of copies of DNA and mutational status of *BRAF* and *NRAS* in melanomas from variable groups in which the degree of exposure to UV light differed.[28] The genetic alterations identified in melanomas at different sites with different levels of sun exposure indicated that there are distinct genetic pathways in the development of melanoma. This supports the hypothesis that the clinical heterogeneity notable for melanoma may be explained by genetically distinct types of melanoma with different susceptibility to UV light.[28] Certainly, other as yet unknown pathways may exist that are independent of UV light.

CLINICAL FINDINGS

Sub-Types of Melanoma

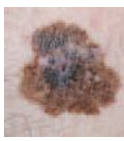
SUPERFICIAL SPREADING MELANOMA SSM is the most common sub-type, accounting for approximately 70 percent of all cutaneous melanomas. It is diagnosed most commonly in the fourth and fifth decades on intermittently sun-exposed areas, most frequently the lower extremity of women, and the upper back of men. Its classic clinical appearance best fits into the ABCD criteria (see Making a Diagnosis), with irregular borders and irregular pigmentation, but it may present subtly as a discrete focal area of darkening within a pre-existing nevus. The range of appearance of SSM is broad (Figs. 124-1 and 124-2). Although varying shades of brown typify most melanocytic lesions, striking aspects of dark brown to black, blue-grey, pink, red, and grey-white (which may represent regression) may be found in melanoma. SSM is the sub-type of melanoma most commonly associated with pre-existing nevi. The history of SSM is often of a lesion slowly changing over months to years. It may be mistaken for an atypical nevus or seborrheic keratosis.

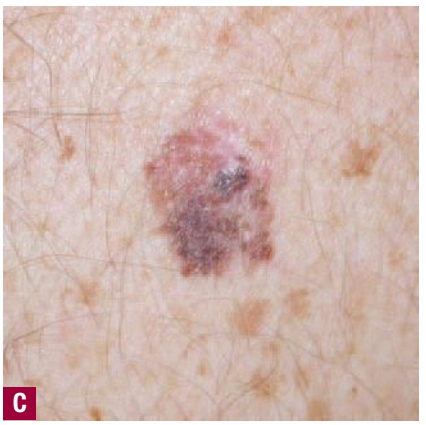
DIFFERENTIAL DIAGNOSIS (Box 124-1)

NODULAR MELANOMA Nodular melanoma (NM) is the second most common melanoma sub-type and accounts for approximately 15 percent to 30 percent of all melanomas. The median age of onset is 53 years, and the trunk is the most common site. NM is remarkable for rapid evolution, often arising over several weeks to months. NM clinically lacks an apparent radial growth phase. It is more common for NM to begin de novo than to arise in a pre-existing nevus. NM typically appears as a uniformly dark blue-black or bluish-red raised lesion, but 5 percent are amelanotic (Fig. 124-3). A substantial proportion of thick melanomas are of the nodular type.[35] Early lesions often lack asymmetry, have irregular borders, and are a size > 6 mm. Amelanotic lesions may be mistaken for basal cell carcinoma, pyogenic granuloma, or hemangioma, whereas pigmented lesions may be mistaken for blue nevi or pigmented basal cell carcinomas.

DIFFERENTIAL DIAGNOSIS (Box 124-2)

LENTIGO MALIGNA AND LENTIGO MALIGNA MELANOMA LM is a sub-type of melanoma in situ with a prolonged radial growth phase that may progress to invasive LMM with time. Invasive LMM constitutes 10 percent to 15 percent of cutaneous melanomas. LM and LMM are diagnosed most commonly in the seventh to eighth decades in an older population than other types of melanoma; they are uncommon before the





◀ **FIGURE 124-1** Superficial spreading melanoma (SSM). **A.** Classic clinical appearance with cardinal features of SSM: asymmetry, irregular scalloped borders, mottled variegate color, large diameter, and central elevation with surface distortion in a 45-year-old man, left chest, Breslow depth 1.25 mm. **B.** Another SSM with similar features but with pronounced areas of pink, shades of blue and white, with peripheral areas of black and brown in a 54-year-old woman, right lower abdomen, Breslow depth 3.5 mm, 26 mitoses/mm^2, ulceration focally present. **C.** Earlier detection in a 55-year-old man with many atypical nevi, patient unaware of the lesion, lesion noted by primary care physician during a routine physical examination, "different" than other nevi, right upper back, Breslow depth 0.50 mm. The pink/tan upper portion is an atypical nevus, the lower portion SSM arising in an atypical nevus. **D.** Still earlier detection with more subtle ABCDs (asymmetry, border, color, diameter/difference, elevation/evolving), forearm, Breslow depth 0.14 mm. The lesion was 0.8 cm in diameter with a history of a "brown spot," which grew in size, changed shape, and changed to a darker color over several months.

age of 40 years. The most common location is on the chronically sun-exposed face, on the cheeks and nose in particular; the neck, scalp, and ears are also involved in men. Its pathogenesis is thought to be related to cumulative sun exposure rather than intermittent exposure. LM is a flat, slowly enlarging, brown, freckle-like macule with irregular shape and differing shades of brown and tan, usually arising in a background of photodamage (Fig. 124-4). The life-

time risk of LMM developing from LM is estimated to be low but the invasive component is potentially lethal.[36] LMM is frequently larger than LM and may continue to be macular in early lesions, although a nodular portion is often seen within the patch later. Both LM and LMM often have clinically ill-defined borders, which may be obscured by background actinic damage consisting of lentigines, pigmented actinic keratoses, or ephelides. LM and LMM are associated with significantly higher rates of extensive sub-clinical lateral growth, resulting in higher recurrence rates with standard recommended margins and failure to completely excise the lesion. LM and LMM have the least common association with nevi, at 3 percent of cases, but the highest rate of association with desmoplastic melanoma (DM).

DIFFERENTIAL DIAGNOSIS (Box 124-3)

ACRAL LENTIGINOUS MELANOMA Acral lentiginous melanoma (ALM) is a sub-type of melanoma with distinct differences in frequencies seen between ethnic groups. ALM constitutes only 2 percent to 8 percent of melanomas in Caucasians but represents the most common form in darker-pigmented individuals (60 percent to 72 percent in blacks, 29 percent to 46 percent in Asians). Although the proportion of ALM seen in darker-pigmented individuals is higher, the incidence of ALM is similar for Caucasians and other ethnicities. ALM is diagnosed in an older population, with the median age of onset being 65 years old. The most common site for ALM is the sole, with the palm and subungual locations following (Fig. 124-5). Not all palmar or plantar melanomas are ALMs; a minority are SSMs or NMs. The clinical appearance of ALM can be brown, black, tan, or red with variegations in color and irregular borders; however, the most common color is brown-black. There is often a delay in the diagnosis of ALM, often misdiagnosed as a plantar wart or hematoma, leading to a more advanced lesion upon diagnosis associated with poorer outcomes.[37] ALM is not thought to be associated with sun exposure.

Subungual melanoma, considered a variant of ALM, generally arises from the nail matrix, most commonly on the great toe or thumb (Fig. 124-6). It appears as a brown to black discoloration or growth in the nail bed. A widening, dark, or irregularly pigmented longitudinal nail streak (melanonychia striata) with or without nail dystrophy and nail plate elevation may be seen. Hutchinson sign, the finding of pigmentation of the posterior nail fold, has been considered an ominous finding associated with advanced subungual melanoma. Benign lesions that can mimic subungual melanoma include

longitudinal melanonychia, subungual hematoma, or pyogenic granuloma or even onychomycosis with pigmentation or hemorrhage.

DIFFERENTIAL DIAGNOSIS (Box 124-4)

Other Variants

DESMOPLASTIC MELANOMA DM is an uncommon type of melanoma that is locally aggressive with high rates of local recurrence. It most commonly develops in older persons, usually in the sixth or seventh decade, and has a male predominance 2:1. The sun-exposed head and neck regions are the most common sites. The lesions typically have a firm, sclerotic, or indurated quality, and one-half are amelanotic (see eFig. 124-6.1 in on-line edition). Approximately one-half of the lesions arise in association with the LM histologic sub-type. Many DMs are deeply invasive at diagnosis and have a propensity to infiltrate perineurally, otherwise called *neurotropic melanoma*. Neurotropism enhances the likelihood of local recurrence. Occasionally, there are some lesions with prominent perineural invasion and no evidence of an intraepidermal component. These lesions are designated *neurotropic melanoma*. Although deeply invasive, DM is associated with lower metastatic rates than other sub-types of melanoma when matched for depth of invasion. A recent study has shown that lesions with fusiform and/or epithelioid melanoma cells had a higher metastatic rate than those with pure DM with only fibrosing component.[38] Results from a small study that involved 10 samples that investigated gene expression profiling demonstrated a molecular distinction between DM and nondesmoplastic melanoma.[39]

Box 124-3

MUCOSAL MELANOMA Melanoma infrequently can arise on mucosal surfaces. The most common sites are the head and neck (conjunctival, intranasal, sinus, and oral cavities), vulva, anorectal, or even urethral melanoma (Fig. 124-7). With the exception of the conjunctiva, patients present most often with delayed detection and a deeply pigmented, irregular lesion, but due to its location, may also present with bleeding or a mass lesion.[40] As most of these lesions present with a radial growth phase manifesting a macular pigmentation, any suspicious area in these sites should be biopsied. Lesions of the conjunctiva are easily visible and appear increased in patients with atypical nevus.[41,42]

NEVOID MELANOMA Nevoid melanoma describes a heterogeneous group of rare lesions that histologically resemble benign nevi by their symmetry and apparent maturation with descent in the dermis, thus with greater potential for misdiagnosis. Clues to their histologic diagnosis include marked hyperchromasia of the nuclei of the tumor cells, the presence of mitoses, and an expansile

growth of the dermal cells with effacement of the adventitia in affected areas. Clinically this may correspond to a tan papule or nodule, more often > 1 cm in diameter on a young adult.[43]

SPITZOID MELANOMA Spitzoid melanoma is a sub-type of melanoma that clinically and histologically resembles a Spitz nevus (see Chap. 122), but tends to be larger and have asymmetry and irregular coloration. Distinction between the two is sometimes extremely difficult, especially in the younger patient with mitoses favoring melanoma. In this tumor, the size of the lesion, greater than 1 cm in diameter; thickness of the invasive component, well over 2 mm; and quite numerous mitoses, many atypical; are helpful in identifying these lesions. The role of *BRAF* or *NRAS* is less clear in the pathogenesis of Spitzoid melanoma.[44]

OTHER RARE TYPES Several other rare and unusual types of melanoma are beyond the scope of this chapter, but previously reported in a comprehensive review, which include metaplastic melanoma, balloon cell melanoma, signet-ring cell melanoma, myxoid melanoma, rhabdoid melanoma, minimal-deviation melanoma, animal-type melanoma, malignant blue nevus.[43]

▲ **FIGURE 124-6** Subungual acral lentiginous melanoma (ALM). **A.** Extensive involvement of periungual skin (Hutchinson sign) with dystrophy and loss of the nail plate secondary to the tumor. **B.** ALM great toe, without notable Hutchinson sign, Breslow depth 3.4 mm, 6 mitoses/mm^2, two positive sentinel nodes identified, disease free at 2 years. **C.** Advanced subungual ALM with proximal periungual macular component and subungual and distal ulcerated nodular component. **D.** Subungual ALM, thumb nail bed streak, Breslow depth 0.5 mm. This was her fourth primary melanoma, other three located on the shoulder, cheek, and neck, the first 14 years prior.

Melanoma and Pregnancy

Melanoma is the second most common cancer in women of child-bearing age, and so it also constitutes one of the more common types of cancers diagnosed in pregnancy.[3,45] There has been much controversy regarding the effect of pregnancy on the clinical course of melanoma. The biologic basis of potential hormonal ef-

fects on melanoma includes the well-known hyperpigmentation associated with pregnancy, and the elevation of many endogenous hormones, including estrogens and melanocyte-stimulating hormone. However, the literature demonstrates that pregnancy before, during, or after a woman is diagnosed with melanoma does not appear to influence overall survival.[46] Overall survival in pregnant women is similar to nonpregnant women diagnosed with melanoma when corrected for prognostic factors; in addition, pregnancy subsequent to the diagnosis of primary melanoma is not associated with an increased risk of death.[47] There is no difference in the distribution of disease stage of melanoma, tumor thickness, lymph node positivity or assessment, and survival for pregnancy-associated melanoma (i.e., melanoma diagnosed during or within 1 year).[48] Pregnant women with melanoma should be offered the same surgical treatments, including sentinel lymph node (SLN) biopsy (usually with omission of blue dye), as nonpregnant counterparts; however, certain chemotherapeutic and immunologic regimens used in advanced melanoma may be contraindicated in pregnancy. After the initial diagnosis and treatment of melanoma, there are no standard, defined guidelines for patients who desire to become pregnant. Counseling recommendations should be comprehensive and individualized on a case-by-case basis, depending primarily on the risk of recurrence (related to the stage at diagnosis) and degree of personal desire to become pregnant relative to risk. Waiting for a period of up to 5 years is generally advised, depending on these factors.

Pediatric Melanoma

Melanoma in childhood and adolescence is rare. Of all newly diagnosed melanomas, 1 percent to 4 percent occur in patients younger than 20 years of age, and only 0.3 percent to 0.4 percent occur in prepubertal children.[49] However, melanoma is being increasingly diagnosed in this age group and being reported to occur more commonly without the classic predisposing risk factors of familial melanoma, congenital nevi, dysplastic nevi, and xeroderma pigmentosum.[50] Based on SEER data of 1255 melanoma patients less than 20 years of age, a 2.9 percent increase in the incidence of pediatric melanoma per year from 1973 to 2001 has been noted; the rate of increase was lower (1.4 percent) in young children less than 10 years.[51] Factors conferring risk of adult melanoma, including increasing age, UV exposure, and Caucasian background, were also found to be important in pediatric melanoma. The classic predisposing factors for adult melanoma are likely to be applicable to some proportion of children. In general, pediatric melanomas tend to have a greater proportion of thicker primaries, possibly related to delayed diagnosis compared with adults.

Making a Diagnosis

Early detection is the key to improving prognosis in melanoma. Although melanoma may have a characteristic appearance, there is no single clinical feature that ensures or excludes a diagnosis of melanoma. Even among expert dermatologists, the clinical diagnosis of melanoma can be made in only about 80 percent to 90 percent of cases. The well-known ABCD acronym for melanoma detection was developed in 1985 and continues to be a useful tool for the lay public and physicians.[52] A stands for asymmetry (one half is not identical to the other half); B for border (irregular, notched, scalloped, ragged, or poorly defined borders as opposed to smooth and straight edges); C for color (having varying shades from one area to another); and D for diameter (i.e., greater than 6 mm, approximately the size of a pencil eraser). Lesions having these characteristics may potentially represent melanoma. Studies have found the sensitivity of the ABCD checklist (Box 124-5) to be in the 90 percent to 100 percent range, but the specificity much lower.[53] NM is notable for the frequency it is overlooked using the ABCD rule; it tends to have smooth borders, be evenly colored, and may be small (less than 6 mm) especially in the early stage. Another diagnostic aid that is useful in detecting melanoma is the "ugly duckling" sign.[54] A pigmented lesion that is different from other pigmented lesions on a particular individual should be approached with a high index of suspicion. This is based on the premise that within an individual, nevi should globally share a common appearance or family resemblance. Even in an individual with multiple atypical nevi, the nevi should be morphologically similar.

History is very important in the evaluation of a lesion. The ABCD rule is relatively static and does not account for a critical element of change. For this reason, some have added an E to the ABCD

Box 124-5

ABCD Checklist[a]

- A = Asymmetry
- B = Border
- C = Color
- D = Diameter/Difference
- E = Elevation/Evolving

[a]Does not apply to nodular melanoma.

rule, where E stands for evolving.[55] Others have advocated for the D to stand for "difference" (i.e., a change in appearance or symptomatology over time or difference from the other lesions, similar to the "ugly duckling" sign). Change in color and increase in size (or a new lesion) are the two most common early characteristics noticed by patients that may be useful in discriminating between melanoma and other benign lesions.[56] In addition to change in color, size, or shape/elevation, persistent lesional itching is also an earlier (albeit non-specific) symptom; ulceration, bleeding, and tenderness generally signify a more advanced primary lesion.[57] Therefore, it is important to ask patients if lesions have changed over time, and to pay particular attention to changing or symptomatic lesions. The development of a new pigmented lesion, especially in an individual beyond the age of 40 to 50 years old and on an anatomic site without similar lesions, is also worthy of suspicion.

Physical Examination

The skin examination should be conducted under optimal lighting and encompass the entire skin integument, including the scalp, external ocular/conjunctivae, oral mucosa, genitalia, buttocks, and palms/soles/web spaces. Melanomas in hidden anatomic sites are associated with thicker tumors at diagnosis, often due to later detection.[58] A global assessment of an individual's skin, including number of nevi, both typical- and atypical-appearing, and distribution of nevi should be noted. Other risk factors, such as a family or personal history of melanoma or previously biopsied atypical nevi, should also be noted. Total body and lesional photography may be useful, especially in high-risk patients with numerous nevi.[59] The use of photography to document the appearance of skin lesions (or the absence of a skin lesion) can allow for better and earlier detection of a changing or new lesion. In high-risk patients, a proportion of melanomas are diagnosed with the aid of photographic surveillance rather than being noted by the patient or even the physician.[60] If a lesion suspicious for melanoma is found on skin examination, palpation of the regional lymph nodes should be performed to evaluate for lymphadenopathy.

Dermoscopy

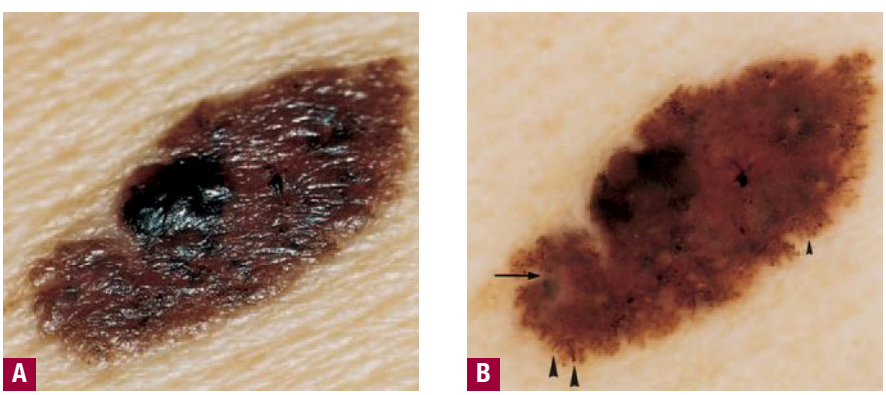
Dermoscopy (also known as *epiluminescence microscopy*, *dermatoscopy*, *incident light microscopy*, and *surface microscopy*) is a simple, non-invasive technique in which a liquid, usually immersion oil, is applied to the lesion, which is then examined with a hand-held lens (magnification usually 10×) or a commercially available device. In experienced hands, it improves both the sensitivity and specificity for the clinical diagnosis of melanoma and other pigmented and non-pigmented lesions, although those without experience and the appropriate training do not realize this benefit. Morphologic features that are otherwise not visible to the naked eye are observed using this technique. Approximately 23 percent of dermatologists in a 2002 report the clinical use of dermoscopy.[61] Its use and popularity as an adjunct to the clinical examination are increasing for both dermatologists and non-dermatologists. Many enthusiastic investigators continue to advance the field of dermoscopy with efforts to improve, refine, and standardize terminology; and simplify the diagnostic categories of pigmented skin lesions.

A new terminology and set of criteria have subsequently been developed for dermoscopy. The *pigment network*, seen as a series of pigmented lines, identifies a pigmented lesion as being melanocytic; it correlates to pigment along rete ridges, both in the basal layer and nests along the dermal-epidermal junction. A typical pigment network pattern has regular delicate lines with gradual thinning at the periphery; whereas an atypical pigment network pattern has irregular, variable, and widened lines that end abruptly at the periphery. *Brown globules* correlate with pigmented nests of melanocytes in the papillary dermis; *black dots* are focal collections of melanocytes and clumps of melanin in the stratum corneum. A *blue-grey veil* represents regression in melanoma. Different diagnostic algorithms using dermoscopic findings have been developed for melanoma, including the ABCD rule, and the 7-point checklist.[62] Pattern analysis, which provides an overall impression of multiple dermoscopic patterns without rigid rules, based primarily on a subjective, simultaneous evaluation of a number of different criteria, is probably the most widely used among experienced experts of dermoscopy. Lists of the important dermoscopy features with clinical pathologic correlations and significance have been widely published and are relatively easily obtainable through courses, societies, and the Internet. Fig. 124-8 summarizes several of these features.

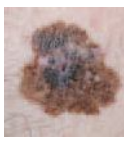
Digital dermoscopy, or digital epiluminescent microscopy, is an advance in non-invasive technology; it permits computerized digital dermoscopic images to be retrieved and examined at a later date so that comparisons can be made and changes detected over time (Fig. 124-9). There are also a number of commercially available automated computer image analysis programs, devices that incorporate image analysis algorithms to digital dermoscopic images, providing objective measurement of changes over time. The use of automated instruments for the diagnosis of melanoma is in an evolving phase. The use of body or lesional photography, professionally obtained or taken by the patient, is also very useful to aid physicians and patients for following lesions, particularly in patients with many nevi.

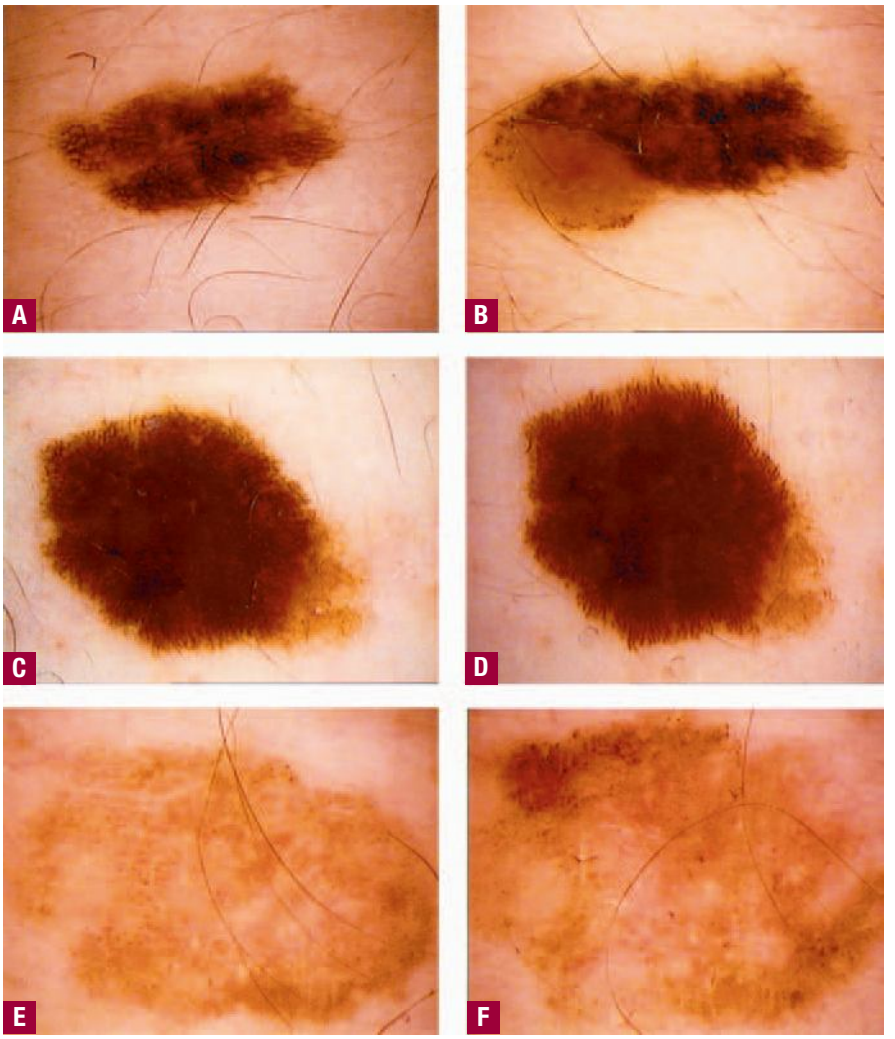
Histopathology

The gold standard for diagnosing melanoma is based on histopathologic evalua-



▲ **FIGURE 124-8** **A.** Superficial spreading melanoma as viewed by close inspection with a hand-held lens or a dermoscope without oil immersion. **B.** With oil immersion, new features become apparent, such as the pigment network, brown globules (*small arrowhead*), pseudopods (*large arrowheads*), and depigmentation, extending irregularly to the periphery of the lesion (*arrow*). (Used with permission from Michael Binder, MD.)





▲ **FIGURE 124-9** Monitoring of atypical nevi (AN) by digital epiluminescence microscopy. All lesions are from patients with multiple atypical nevus syndrome. **A.** Image of AN at time of presentation. The lesion shows features of an AN and, because the patient has multiple such lesions, clinical monitoring at 6-month intervals was scheduled. **B.** Follow-up of the same lesion after 8 months. The lesion has changed. There is asymmetric increase in size and the appearance of a new hypopigmented structure at the periphery on the left. The lesion was excised and histology revealed AN in the right portion of the lesion and superficial spreading melanoma (SSM) < 0.75 mm on the left. **C.** This AN is more difficult to evaluate. Typical AN at baseline (**C**) but after 6 months, (**D**) subtle changes have occurred. There is an increase in size, albeit symmetric, of the lesion, but the pigment network at the upper and lower margin has transformed into a fringe of fine pseudopods suggesting SSM. Histology confirmed SSM < 0.75 mm. **E.** Another AN at baseline. **F.** Follow-up image of the same lesion at 6 months. The most prominent changes are asymmetric increase in size, appearance of a new irregular pigment network, dots, and globules at the upper left margin of the lesion. Histology revealed SSM < 0.75 mm. (Used with permission from Harald Kittler, MD.)

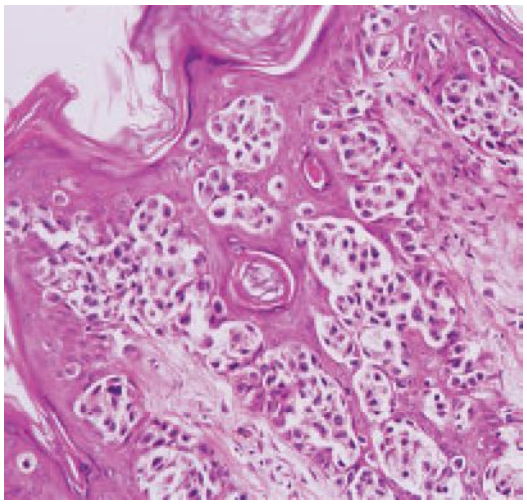
tion of the biopsy specimen, preferably by a dermatopathologist or a pathologist experienced with pigmented lesions. There is some histologic diagnostic discordance in the diagnosis of melanomas and melanocytic lesions, especially with early melanomas, even among experts, but the percentage of cases in which the diagnosis changes from benign to malignant or vice versa, or would result in a major modification in therapy or prognosis, is small.[63–65] The histologic diagnosis of melanoma is based on the assessment of a constellation of findings, including both architectural and cytologic features. No single feature is diagnostic. Cytologic atypia, referring to cellular enlargement, nuclear enlargement, nuclear pleomorphism, hyperchromasia of nuclei, nucleolar variability, and the presence of mitoses especially deep in the dermis, is considered necessary for a diagnosis of melanoma. The major architectural features of melanoma include asymmetry, poor circumscription (i.e., cells at the edge of the lesion tend to be small, single, and scattered), and large size (> 5 to 6 mm). Nests of melanocytes in the lower epidermis and dermis tend to vary a good deal in size and shape, and to become confluent. There is a lack of maturation of nests with descent into the dermis. Pagetoid spread of large solitary epidermal melanocytes, usually considered diagnostic of melanoma, should be assessed cautiously in the context of other findings, as pagetoid spread may be seen in benign lesions including Spitz nevi, spindle cell nevi, vulvar nevi, and acral nevi.

The different sub-types of melanoma have histopathologic differences as well. SSM is characterized by a population of melanocytes appearing uniformly atypical (Figs. 124-10 and 124-11). LM and LMM are characterized by atypical melanocytes singly and in nests, predominantly confined to the basal layer of the epidermis, which become confluent without pagetoid spread, occurring in the background of photodamage (Figs. 124-12, 124-13, and 124-14). The cells may extend down hair follicles and appendageal structures. The epidermis is thin and atrophic, with loss of rete ridges. There is variable cytologic atypia. The "lentiginous" in ALM is derived from the characteristic lentiginous pattern of most cells being single and located near the dermal-epidermal junction (Fig. 124-15). ALM differs from LM in that there is irregular acanthosis, and the melanoma cells are uniformly malignant and often dendritic. In LM, the cells are highly pleomorphic in an atrophic epidermis. NM demonstrates little tendency for intraepidermal growth; instead, there is a dermal mass of atypical melanocytes (Figs. 124-16 and 124-17). DM is composed of strands of elongated, spindle-shaped cells that often infiltrate deeply. Neurotropic melanoma describes a subset of DMs in which the cells invade perineurally and form patterns resembling nerves.

The typical pathology report useful for management includes creation of a 14-point melanoma profile shown in Box 124-6.

Immunohistochemistry

Immunohistochemistry may be useful for the diagnosis of melanoma, especially in poorly differentiated neoplasms with little or no pigment (i.e., amelanotic melanomas), spindle cell tumors, or tumors with pagetoid spread that are not obviously melanoma. S100 protein is ex-



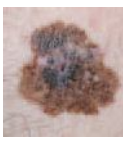
◀ **FIGURE 124-10** Superficial spreading melanoma. This tumor shows intraepidermal growth. In this photomicrograph, the pagetoid distribution is evident in the epidermis. The cells are relatively uniform and have an abundance of dusty, fine pigment. These relatively large melanoma cells are frequently referred to as epithelioid cell type.

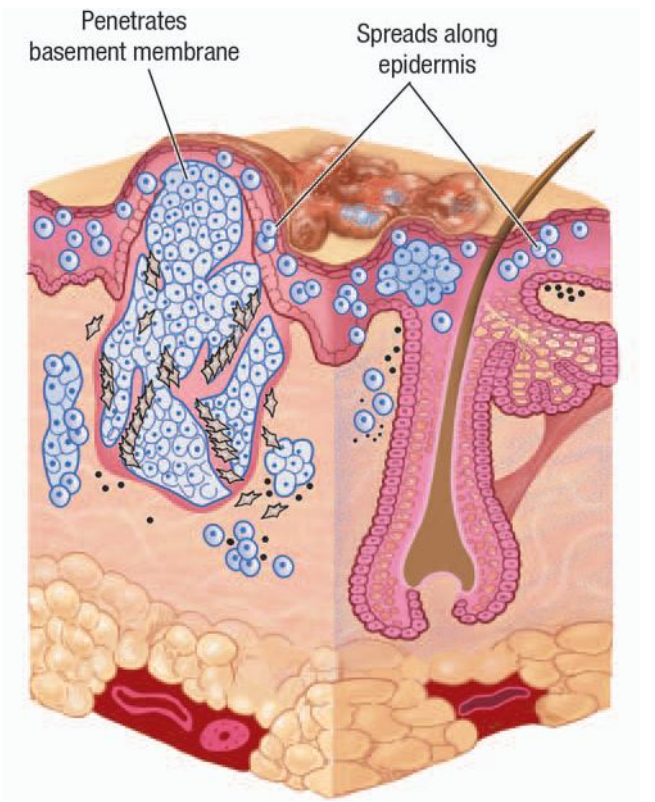
pressed by virtually all melanomas, but also by melanocytic nevi, Langerhans cells, and cutaneous neural tumors. HMB-45 is a monoclonal antibody with high specificity for melanoma cells, although it is frequently negative in DM; DMs commonly exhibit vimentin and S100 positivity. Melan-A and MART-1 (melanoma antigen recognized by T cells) are the names given independently to the same gene encoding a melanocytic differentiation antigen expressed in skin and retina but not other normal tissues. Melan-A is broadly expressed in benign and malignant melanocytic lesions but not in most DMs. It is more sensitive than HMB-45 and more specific than S-100 for melanoma. Search for the microphthalmia-associated transcription factor (Mitf) may be extremely useful, especially in amelanotic melanomas, as it is a marker in the nucleus, whereas all other markers are intracytoplasmic.[66] It stains most melanomas except for DM where staining is usually negative but variable.

PROGNOSIS AND CLINICAL COURSE

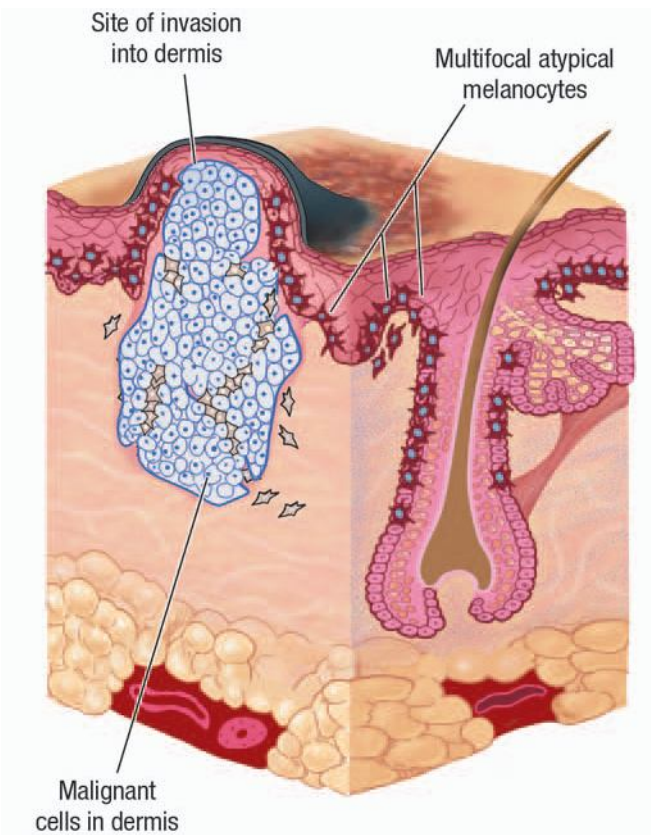
Staging and Prognostic Factors

Accurate staging of melanoma is essential for determining optimal treatment and for assessing prognosis. Accurate staging forms the basis for prognosis and treatment, which is invaluable for the majority of patients in their informed decision-making process. The American Joint Committee on Cancer (AJCC) revised the staging system for melanoma in 2002 with several fundamental changes,[67] which incorporates the most

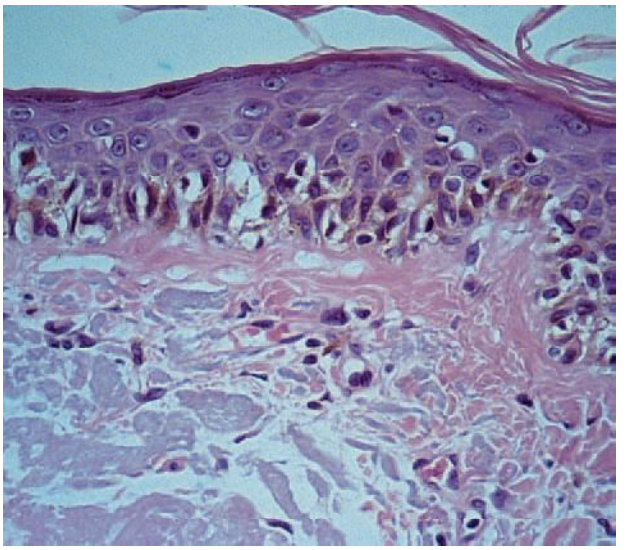




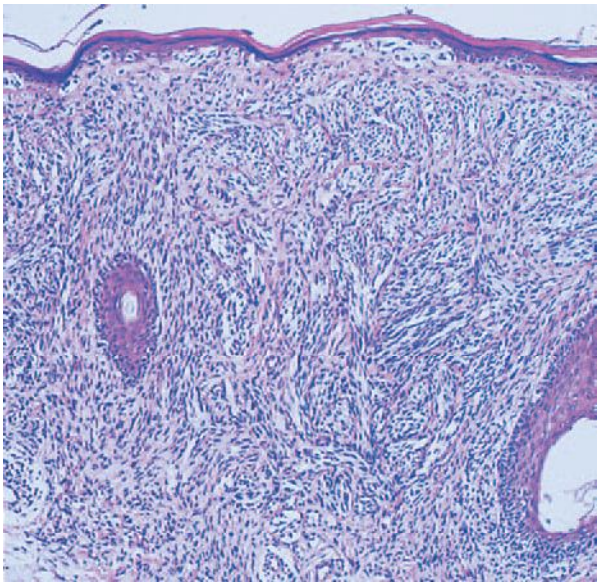
▲ **FIGURE 124-11** Superficial spreading melanoma. The border is irregular, and the lesion is elevated throughout its entirety. Biopsy of the area surrounding the large nodule shows a "pagetoid" distribution of large melanocytes that are occurring singly or in nests, and uniformly atypical. On the left is a large nodule, and scattered throughout the surrounding portion of the nodule are smaller popular and nodular areas. The nodule on the left shows malignant melanocytes that are very large, have an abundance of cytoplasm, and often have regularly dispersed fine particles of melanin. The nodules may also show spindle cells or small malignant melanocytes as in lentigo maligna melanoma and nodular melanoma.



▲ **FIGURE 124-12** Lentigo maligna melanoma. Illustrated on the right is a large, variegated, freckle-like macule (not elevated above the plane of skin) with irregular borders; the tan areas show increased numbers of melanocytes, usually atypical and bizarre, and are distributed single file along the basal layer; at certain places in the dermis, malignant melanocytes have invaded and formed prominent nests. At the left is a large nodule that is composed of epithelioid cells in this illustration; the nodules of all four main subtypes of melanoma are indistinguishable from each other.



▲ **FIGURE 124-13** Lentigo maligna. This is a proliferation of pleomorphic melanocytes in the basal layer of an atrophic epidermis in sun-damaged skin.



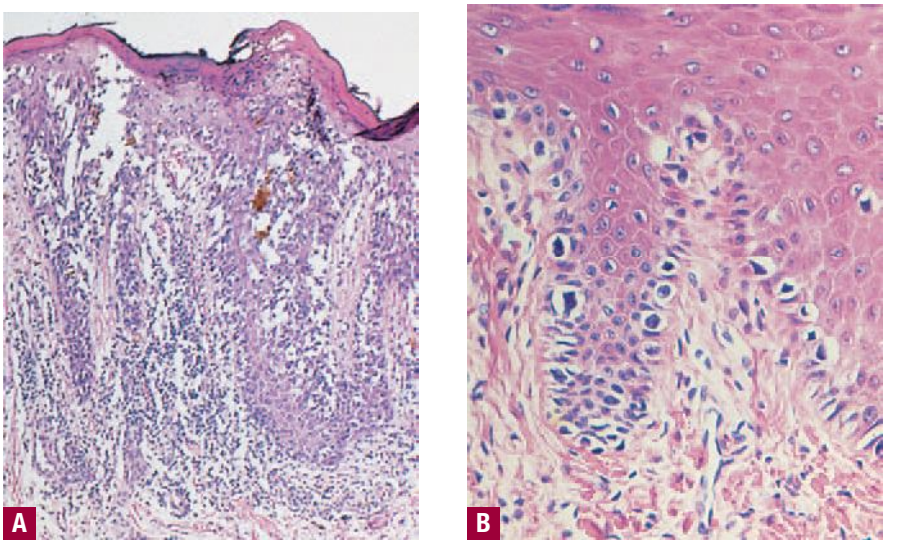
▲ **FIGURE 124-14** Lentigo maligna melanoma. Extending from the epidermis into the dermis are numerous elongated melanocytes. In lentigo maligna melanoma, these cells are frequently spindle-shaped.

important prognostic factors, such as microstaging and nodal status, and translates them into reported survival rates. It is well recognized that the current staging classification system is not perfect, and plans for the next revision are anticipated in 2009. In spite of some drawbacks, the current staging system is clinically valuable and should be used, particularly in clinical trials, reports, and studies to make data comparable. Multicenter retrospective data from 17,600 patients with melanoma were used to determine the significant prognostic variables in the current AJCC classification system.[68] T describes the extent or thickness of the primary tumor, N the extent of lymph node metastases, and M the extent of distant metastases. Table 124-2 presents the TNM categories (*t*umor size, *n*ode status, *m*etasasis classification), and Table 124-3 lists the stage groupings. There are five stages based on prognosis: stage 0 (in situ disease), stages I and II (localized disease), stage III (regional disease), and stage IV (distant metastatic disease). In general, prognosis and survival rates worsen with increasing stage (Table 124-4). At initial presentation, approximately 85 percent of patients have localized disease (stages I and II), 10 percent have regional metastatic disease, and 5 percent have distant metastatic disease.[67]

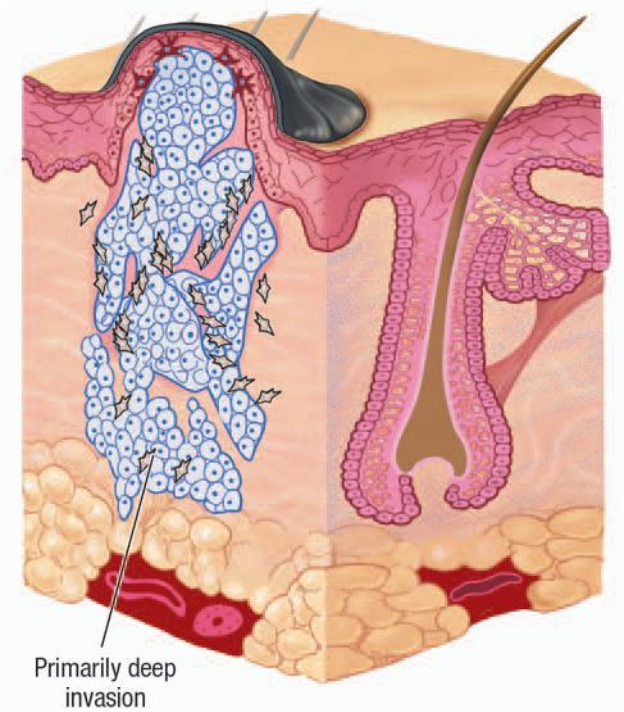
Prognostic Factors in Microstaging (See Table 124-4)

TUMOR THICKNESS The single most important prognostic factor for survival and clinical management in localized stage I and II cutaneous melanoma is tumor thickness.[68] As originally described by Breslow, thickness is measured from the top of the granular layer of the epidermis to the greatest depth of tumor invasion using an ocular micrometer and measured in millimeters (see eFig. 124-17.1 in online edition). Survival decreases with increasing Breslow depth. Clark level is an alternate, less accurate method of depicting tumor thickness by the anatomic level of invasion and is less important in current microstaging. Historically described by Clark, melanoma is confined to the epidermis in level I, extends into the papillary dermis in level II, accumulates in and expands in the papillary dermis in level III, extends into the reticular dermis in level IV, and invades the subcutaneous fat in level V (see eFig. 124-17.1 in on-line edition). Clark level of invasion may have an impact on survival for thin melanomas < 1 mm, when a Clark level of IV or V upstages a melanoma from T1a to T1b. However, other data suggest that, compared to Breslow depth, Clark level is a weaker prognostic indicator for survival.[69]

ULCERATION Ulceration also currently represents an independent prognostic



▲ **FIGURE 124-15** Acral lentiginous melanoma. **A.** Photomicrograph showing hyperkeratosis associated with plantar location of this melanoma. Fibrosis and patchy host response are noted in the dermis. **B.** High-powered photomicrograph showing lentiginous proliferation of abnormal melanocytes along the dermal-epidermal junction.



▲ **FIGURE 124-16** Nodular melanoma. This tumor arises at the dermal-epidermal junction and extends vertically into the dermis; intraepidermal growth is present only in a small group of tumor cells that conjointly are also invading the underlying dermis. The epidermis lateral to the areas of this invasion does not demonstrate atypical melanocytes. As with lentigo maligna melanoma and superficial spreading melanoma, the tumor may show large epithelioid cells, spindle cells, small malignant melanocytes, or mixtures of all three.

factor for localized melanoma in the AJCC study and was highly correlated with survival.[68] The presence of ulceration in the primary confers a higher risk of developing advanced disease and lower survival rate. The presence of ulceration upstages all patients with localized as well as regional disease [i.e., stages I to III (see Table 124-2)]. Ulceration correlates with tumor thickness; it occurs infrequently in thin melanomas (6 percent for melanomas < 1 mm) and frequently in thick melanomas (63 percent for melanomas > 4 mm). Conversely, multivariate analysis of data from the German Central Malignant Melanoma Registry demonstrated ulceration to have a significant negative impact on the prognosis for patients with T2 and T3 lesions, but not for T1 and T4. For stage III regional disease, the impact of ulceration on overall survival was significant in bivariate but not multivariate analysis. In spite of these drawbacks, the new staging classification should be used, particularly in clinical trials, to make data internationally comparable.[70] One potential shortcoming of ulceration as a variable is that ulceration is not always a homogeneous phenomenon and may result from trauma, which is prognostically insignificant. For this reason, ulceration should only be reported when there is evidence of host response at the site, including fibrin and nuclear debris. Their presence indicates a preoperative event not possibly associated with artifactual causes due to surgery or processing.

MITOTIC RATE There is a growing body of literature and studies to strongly support a significant independent relationship between tumor mitotic rate and prognosis in melanoma. Mitotic rate, measured as the number of mitoses per square millimeter, is usually counted as

TABLE 124-2
Melanoma TNM Classifications[a]

T Classification	Thickness (mm)	Ulceration Status
T1	≤ 1.0	a: without ulceration and level II/III b: with ulceration or level IV/V T2
T2	1.01–2.0	a: without ulceration b: with ulceration
T3	2.01–4.0	a: without ulceration b: with ulceration
T4	> 4.0	a: without ulceration b: with ulceration
N Classification	**Number of Metastatic Nodes**	**Nodal Metastatic Mass**
N1	1	a: micrometastasis[b] b: macrometastasis[c]
N2	2–3	a: micrometastasis[b] b: macrometastasis[c] c: in-transit met(s)/satellite(s) without metastatic nodes
N3	4 or more nodes, or matted nodes, or in-transit met(s)/satellite(s) with metastatic node(s)	
M Classification	**Site**	**Serum Lactate Dehydrogenase**
M1a	Distant skin, subcutaneous, or nodal metastases	Normal
M1b	Lung metastases	Normal
M1c	All other visceral metastases	Normal
	Any distant metastasis	Elevated

TNM = tumor size, node status, metastasis classification.
[a]Six major changes are included in the 2002 version of American Joint Committee on Cancer melanoma staging system:
1. Anatomic level is used only in the staging of thin tumors. Thickness and ulceration are primarily used in the T category. The anatomic level of invasion (Clark levels) is currently understood to be an independent prognostic feature only for thin melanomas. As a result, Clark levels are incorporated only into staging of thin melanomas (< 1.0 mm or category T1).
2. Ulceration of the tumor has been added to the staging system. Ulceration is an independent risk factor and portends a higher risk of developing advanced disease. The presence of ulceration "upstages" all patients with stages I to III disease. In a given T grouping, the new system subclassifies patients as "a" for tumors without ulceration, and "b" for tumors with ulceration.
3. The number of metastatic nodes, rather than the size of nodes, is used as a primary criterion in the N staging.
4. The system incorporates a new convention for categorizing patients both clinically and pathologically. This system incorporates date from lymphatic mapping and sentinel node biopsy.
5. In-transit and satellite metastases have been grouped in the same subclassification (N2c). Patients with intralymphatic metastases but no nodal metastases are recognized as having a similar prognosis and are thus grouped together.
6. Distant metastatic melanoma is classified by site(s) of metastases and levels of lactic dehydrogenase detected in serum.

[b]Micrometastases are diagnosed after sentinel or elective lymphadenectomy.
[c]Macrometastases are defined as clinically detectable nodal metastases confirmed by therapeutic lymphadenectomy or when nodal metastasis exhibits gross extracapsular extension.

the number of mitoses seen in five high-power (×40) microscope fields (the equivalent of a 1-mm^2 area), starting in the fields with the most mitoses. Several large studies have reported mitotic rate to be an independent prognostic risk factor in melanoma survival, which will be closely examined in the future revised AJCC staging system.[71,72] Patients with a mitotic rate of 0 mitoses/mm^2 have a significantly better survival than those with ≥ 1 mitosis/mm^2. There may be some variability in the reproducibility of mitotic rate, as it is subject to sampling error in the high-power fields used.

ANGIOLYMPHATIC INVASION Vascular involvement denotes the invasion of tumor cells into the microvasculature in the dermis. Several reports note that vascular invasion significantly increases the risk of relapse, lymph node involvement, distant metastases, and death.[73,74]

OTHER HISTOLOGIC FACTORS Other factors have been variably reported as predictive of prognosis in melanoma including the presence of microsatellitosis, tumor-infiltrating lymphocytes, regression, tumor lymphangiogenesis (i.e., formation of new vessels), and radial versus vertical growth phase. The presence of microscopic satellitosis in particular has been consistently reported with a correlation with poorer outcome and is incorporated into the current AJCC staging system.

Clinical Prognostic Factors

AGE Many studies have reported that increasing patient age portends a worse prognosis with respect to overall survival rates. Males more than 60 years of age have the highest mortality rates from melanoma. Older patients have thicker primaries and a higher proportion of ulcerated melanomas, but even after adjusting for these factors, age appears to be an independent prognostic factor.[3,6,57,74] It has been postulated that age may serve as a surrogate for declining host immune defense mechanisms.

GENDER A large number of studies have reported that women have better survival rates than men, even after adjustment for tumor thickness and anatomic site.

ANATOMIC SITE The anatomic location of primary cutaneous melanomas has been variably reported to affect survival. In the AJCC study, melanomas located on the trunk and head and neck were correlated with worse prognosis than melanomas on the extremities, but the recorded locations were only (1) extremities, or (2) trunk, head, or neck.[68] In another large study of 5093 patients, melanomas on the *ba*ck and thorax, upper *n*eck, and *s*calp (BANS regions) were associated with significantly lower survival rates than melanomas on the lower trunk, thigh, lower leg, feet, lower arms, hands, and face.[75] Nonetheless, anatomic site has not been confirmed as an independent factor in many studies.

Prognostic Factors in Regional Metastasis

The status of the regional lymph nodes is the most powerful prognostic factor for survival in melanoma. The presence of regional lymph node metastasis portends a worse prognosis. The number of lymph nodes involved, independent of size, is the most significant risk factor in

[a]Clinical staging includes microstaging of the primary melanoma and clinical/radiologic evaluation for metastases. By convention, it should be used after complete excision of the primary melanoma with clinical assessment for regional and distant metastases.
[b]Pathologic staging includes microstaging of the primary melanoma and pathologic information about the regional lymph nodes after partial or complete lymphadenectomy. Pathologic stage 0 or stage 1A patients are the exception; they do not require pathologic evaluation of their lymph nodes.
[c]There are no stage III subgroups for clinical staging.

patients with stage III melanoma.[68] The second most important risk factor is tumor burden, stratified into micrometastatic disease as determined by SLN biopsy or imaging scans, and macrometastatic disease (i.e., clinically palpable nodes). In clinically node-negative stage I or II patients, SLN status was the most significant prognostic factor with respect to disease-free and disease-specific survival.[76] As such, SLN biopsy to search for micrometastatic disease has become widely used to obtain prognostic information and is incorporated into the current AJCC staging classification system for melanoma.[67] As mentioned earlier, ulceration of the primary lesion is still a prognostic factor in regional disease, and the presence of ulceration signifies a worse prognosis in stage III disease. Satellite, both clinical and microscopic, metastases around a primary melanoma and in-transit metastases between the primary and its nodal basin represent intralymphatic metastases (N2c or N3) and portend the worst prognosis for regional metastases.

Prognostic Factors in Distant Metastasis

The presence of distant metastases portends the worst prognosis, with mean survival rates measured in months rather than years. Site of metastasis was the most important prognostic factor in the AJCC melanoma study; visceral metastases had a relatively poorer prognosis than non-visceral (skin, subcutaneous tissue, and distant lymph nodes) sites.[68] Other variables of prognostic significance are the number of metastatic sites and surgical resectability. Solitary metastases resected after radiologic demonstration of stability over 3 to 6 months have been associated with prolonged survival in some, but no strong evidence exists that asymptomatic detection is associated with significant overall survival to date.[77] Elevated serum lactate dehydrogenase (LDH) levels are associated with a poorer prognosis.

Clinical Course

STAGES I AND II MELANOMA In general, the prognosis of patients with thin primary melanoma < 1 mm in Breslow depth and localized disease is excellent, with long-term survival achieved in more than 90 percent of patients. However, approximately 15 percent to 36 percent of patients with stages I and II melanoma will have some form of local, regional, or distant recurrence or metastasis during their clinical course. Melanoma typically recurs in a predictable fashion, first in a local and regional distribution, then to distant sites. It is also recognized that melanoma may bypass the regional nodes with direct hematogenous dissemination. The vast majority of recurrences manifest in the first 1 to 5 years after diagnosis and treatment, depending on tumor thickness and other prognostic features of the primary lesion (see Prognostic Factors in Microstaging). However, melanoma can recur at any time, and the incidence of late recurrence 10 or more years after initial diagnosis is approximately 1 percent to 5 percent. Most tumors with late recurrences are of intermediate thickness (mean, 1.6 mm; most in the 0.70 to 3.0 mm range) and occur at a mean of 14.3 years.[78] "Ultra late" recurrences more than 15 years after diagnosis are extremely rare but do occur.[79]

STAGE III MELANOMA Data from the Sunbelt Melanoma Trial with over 1100 melanoma patients indicate that recurrence rates are significantly higher with early stage III melanoma (i.e., micrometastatic nodal disease found on SLN biopsy) than with SLN-negative melanoma (15.5 percent vs. 6.0 percent, respectively).[80] Patients with SLN-positive melanoma were also significantly more likely to have distant metastases (as opposed to locoregional recurrence) versus those with SLN negative (67 percent vs. 46 percent, respectively). Pooled analysis reveals estimated 5-year overall survival rates between 93 percent and 88 percent for patients with a negative SLN, versus between 51 percent and 67 percent for a positive SLN.[81] Stage III melanoma encompasses a heterogeneous population of patients with a marked diversity in clinical course (Fig. 124-18). This is reflected by 5-year survival rates ranging from 70 percent for patients with non-

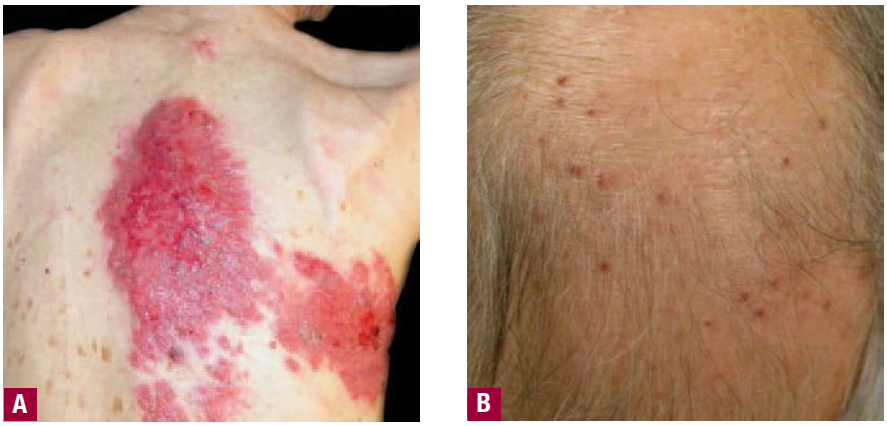
ulcerated primaries and micrometastatic disease in one lymph node, to 25 percent for patients with multiple, matted lymph nodes or in-transit/satellite metastases. The presence of greater tumor burden in the regional lymph nodes is highly predictive of visceral metastases.

STAGE IV MELANOMA Melanoma is well known for its propensity to metastasize to virtually any organ and also for its highly variable clinical course. Melanoma metastasizes to non-visceral sites: distant skin/subcutaneous tissue and distant lymph nodes in approximately one-half of the stage IV cases (42 percent to 57 percent) (Fig. 124-19). The most common visceral sites are the lungs (18 percent to 36 percent), liver (14 percent to 20 percent), brain (12 percent to 20 percent), bone (11 percent to 17 percent) and gastrointestinal tract (1 percent to 7 percent). Once metastases to distant sites have been detected, median survival is approximately 6 to 8 months, and a minority live beyond 1 year.[68]

◀ **FIGURE 124-18** Uncontrollable bulky metastatic melanoma to the regional lymph nodes.

METASTATIC MELANOMA OF UNKNOWN PRIMARY Metastatic melanoma of unknown primary is defined as the presence of histologically confirmed melanoma in a lymph node, visceral site, or distant skin/subcutaneous tissues without a history or evidence of a primary cutaneous, mucosal, or ocular melanoma. This situation occurs in approximately 2 percent to 5 percent of all cases of melanoma. Approximately 60 percent of such metastases involve the lymph nodes, most commonly in the axilla, and the rest involve distant sites, typically the skin/subcutaneous tissue, and less commonly lung, brain, or gastrointestinal tract.[82] Melanoma of unknown primary has similar survival rates compared to equivalently staged melanomas of known primary origin. In the largest study to date, melanoma of unknown primary metastatic to lymph nodes had 5- and 10-year survival rates of 46 percent and 41 percent, which is comparable to the equivalent stage III melanoma of known primary.[83] Melanoma of unknown primary metastatic to viscera had a median survival of 6 months.[84]

Although rare, a handful of cases have been reported in which a solitary melanoma of the skin confined to the dermis or subcutaneous tissue presumed to be metastatic melanoma of unknown pri-



▲ **FIGURE 124-19** **A.** Zosteriform pattern metastases on the back. The primary melanoma was also on the back, Breslow depth 3.9 mm with ulceration and satellitosis. **B.** Epidermotropic and dermal metastatic melanoma on the scalp (also present on the face and neck) occurring 1 year following diagnosis of nodular primary mid-back melanoma, Breslow depth 3.75 mm, sentinel lymph node biopsy positive left and right axilla.

mary has unexpectedly high survival rates.[85,86] *Primary dermal melanoma* is the term used to describe these solitary lesions with 5-year survival rates reported in the 80 percent range. It may represent a distinct sub-type of melanoma actually originating in the dermal and/or subcutaneous tissue.

Evaluation of melanoma of unknown primary or dermal melanoma should involve a complete skin examination looking for a primary site. Wood's lamp may be used to identify sub-clinical hypopigmented areas, which may suggest a regressed primary lesion. In melanoma of unknown primary metastatic to a lymph node, particular attention should be focused on the skin areas that drain to the nodal basin involved. A complete history of previously excised skin lesions should be reviewed. The patient should be referred for proctoscopic, gynecologic, ocular, and nasal mucosal examinations, when warranted. Staging workup and treatment should be performed as for the equivalent clinical stage of known primary.

TREATMENT (Fig. 124-20)

Staging Workup

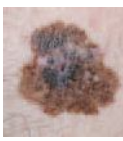
BIOPSY Patients with lesions clinically suspicious for melanoma should, whenever possible, undergo prompt excisional biopsy with narrow margins. A wider margin should be avoided to permit the most accurate subsequent SLN biopsy, if indicated. Most melanomas undergo initial biopsy in their clinical entirety, but if the lesion is large and/or located on certain sensitive anatomic areas such as the palm/sole, digit, face, or ear, an incisional full-thickness to adipose skin biopsy may be performed. An incisional biopsy should be obtained in the most elevated or darkest area of the lesion, with an appreciation that the clinically most suspicious area may not always correlate with the thickest portion of the lesion. There is no evidence that biopsy or incision of a primary melanoma leads to "seeding" of tissue and adversely affects survival. If subtotal incisional biopsy confirms melanoma, and there is significant residual clinical lesion, a narrow margin excisional biopsy should be performed first for accurate microstaging if the patient is a candidate for SLN biopsy. Excisional biopsy performed after incisional biopsy of melanoma with ≥ 50 percent of the lesion remaining resulted in significant upstaging in 21 percent of patients, and change in SLNB consideration in 10 percent of patients, who then became candidates for SLN biopsy.[88]

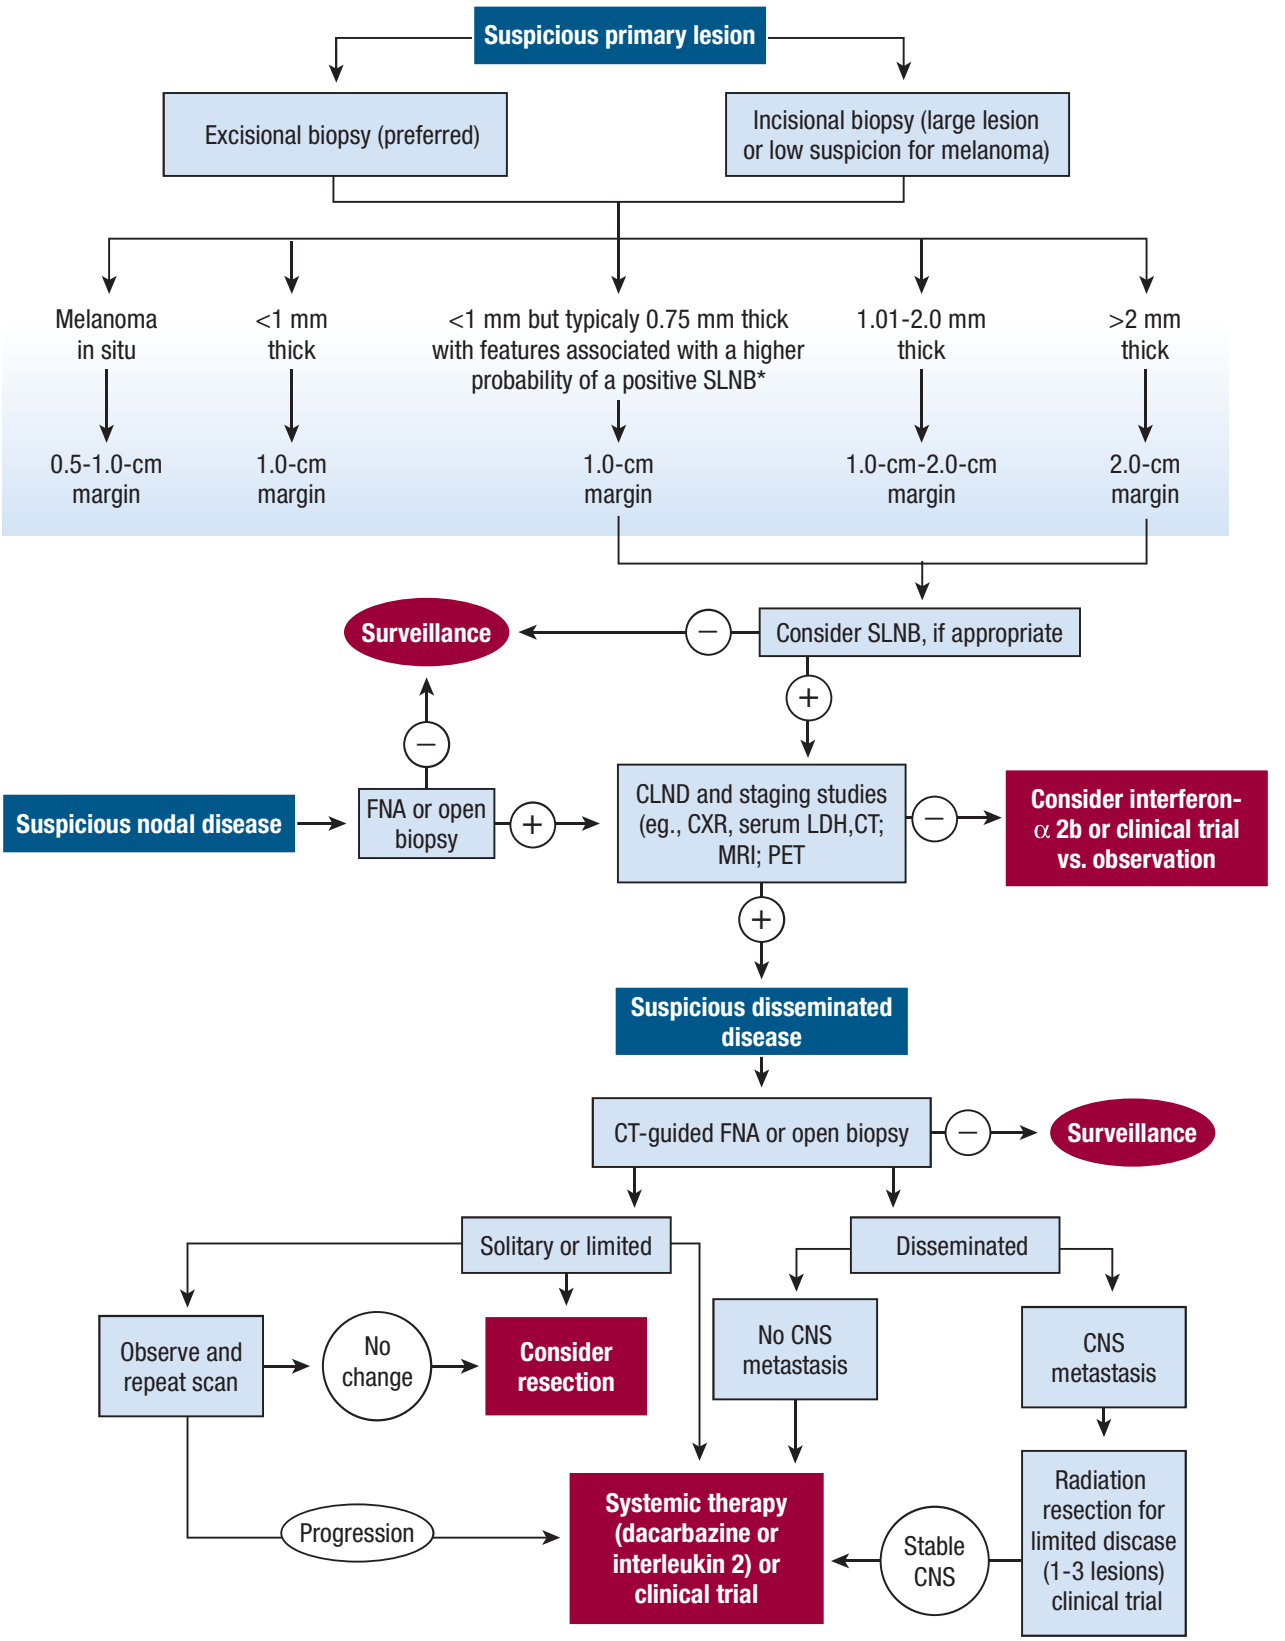
Evaluation for Regional Metastasis

MACROSCOPIC METASTASES The foundation of the initial workup following diagnosis of primary cutaneous melanoma is thorough history taking and physical examination. The findings on a good history and physical examination will, to a great extent, drive any further workup. Patients should be evaluated for regional spread by careful palpation of lymph nodes, particularly the primary echelon nodal basin(s). The concepts of aberrant lymphatic drainage pathways to unexpected nodal basins and interval nodes located between the primary site and the expected regional nodal basin have taught physicians to search for clinically detectable nodal disease in unexpected locations.[89,90] If a palpable lymph node or a dermal/subcutaneous nodule in the regional area of the primary is found, fine needle aspiration may be utilized to make a histological diagnosis supported by the current 2006 National Comprehensive Cancer Network (NCCN) guidelines. An excisional biopsy of the lymph node should be performed if fine needle aspiration is inconclusive or not feasible.[91] Non-invasive imaging, most commonly with ultrasound or computerized or positron emission tomography (PET), is perhaps the most sensitive noninvasive method to detect small nodal metastases. However, the sensitivity and specificity of these tests are inferior to tissue diagnosis obtained with SLN biopsy.[92–94]

MICROSCOPIC METASTASES ***Sentinel Lymph Node Biopsy.*** One of the most significant advances in melanoma management over the last decade is SLN biopsy. It is currently one of the most powerful staging and prognostic tools for a subset of patients with melanoma.[87] SLN biopsy is a staging technique used to detect occult nonpalpable micrometastases in regional lymph nodes. SLN biopsy represents the best baseline staging test for detection of occult nodal metastasis in a relatively small subset where it may be indicated, and the only staging test with both relatively high sensitivity and specificity. There is a small likelihood of identifiable distant disease if the SLN is negative.[95]

In the early 1990s, Morton et al. initially reported the technique to selectively sample the first draining regional lymph node(s), or SLN(s) for melanoma[97]; this SLN is most likely to contain any tumor cells that may have metastasized from the primary.[97] Blue dye injected intradermally at the primary site was identified in the SLNs 90 percent of the time, and 15 percent of the SLNs contained melanoma; subsequent lymphadenectomy found melanoma in only 1 percent of non-SLNs. In current practice, both blue dye and technetium-99-labeled radiocolloid solution are used together; this allows for detection of the SLN > 95 percent of the time in skilled hands. Ideally, the procedure should be performed at the same time as wide local excision (WLE) of the primary melanoma for greatest accuracy. SLN biopsy may not be accurate if performed after WLE in areas of ambiguous lymphatic drainage or following a local skin flap due to radiocolloid and dye injection location away from the true primary site. Once removed, the SLN(s)





▲ **FIGURE 124-20** General guideline algorithm for the treatment of cutaneous melanoma. *Ulceration, extensive vertical regression to at least 1 mm thick, young patient age, high mitotic rate, especially in younger persons, shave biopsy with positive deep margin, presence of angiolymphatic invasion, and Clark level IV. CLND = completion lymph-node dissection; CNS = central nervous system; CT = computed tomography; CXR = chest x-ray; FNA = fine-needle aspiration; LDH = serum lactate dehydrogenase; MRI = magnetic resonance imaging; PET = positron emission tomography; SLNB = sentinel-lymph-node biopsy. A minus sign indicates no evidence of disease, and a plus sign evidence of metastasis. Patients who are candidates for sentinel-lymph-node biopsy should be referred to a surgeon experienced in performing the procedure so that the benefits and complications can be fully discussed. (From Tsao H, Atkins MB, Sober AJ: Management of cutaneous melanoma. *N Engl J Med* **351**:998, 2004; with permission.)

must be assessed with serial sectioning, using standard hematoxylin and eosin (H&E) techniques combined with immunohistochemical stains such as S100, HMB-45 and/or Melan-A if H&E is negative or inconclusive. This increases sensitivity for melanoma and has resulted in the upstaging of up to 20 percent of patients.[98] The SLN biopsy procedure requires the expertise and experience of three disciplines: surgery, nuclear medicine, and pathology.

Current 2006 guidelines call for consideration of SLN biopsy for relatively healthy patients with primary localized melanoma ≥ 1 mm in Breslow depth (see Fig. 124-20).[67] The most important and consistently reported predictor of SLN positivity is Breslow depth. The likelihood of regional nodal involvement rises with increasing tumor thickness. For melanomas < 1 mm, the likelihood of a positive SLN has been reported to be 5 percent to 10 percent; for melanomas 1 to 2 mm, 15 percent to 20 percent; for melanomas 2 to 4 mm, 25 percent to 35 percent; and for melanomas > 4 mm, 40 percent to 50 percent.[76,87,99,–102] The incidence of SLN positivity has increased compared with initial reports, mainly due modifications, experience, and the routine use of immunostains in current practice. As melanomas < 1 mm uncommonly metastasize to lymph nodes, SLN biopsy is not routinely performed. However, SLN biopsy may be considered for thinner lesions 0.75 to 0.99 mm in Breslow depth in the presence of certain adverse features that have been found to increase SLN positivity in thin lesions: ulceration, extensive vertical regression to at least 1 mm, young patient age, high mitotic rate especially in younger persons, shave biopsy with positive deep margin, and the presence of angiolymphatic invasion.[73,100,101,103,104] Clark level IV is still used as an indication for consideration of SLNB by some centers but not by many others.[69]

Evaluation for Distant Metastasis

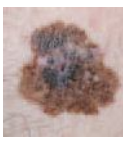
A thorough melanoma-focused review of systems constitutes the foundation of the evaluation for distant metastases with particular attention to the general/constitutional, neurologic, psychiatric, gastrointestinal, musculoskeletal, skin, lymphatic, endocrine, cardiovascular, and respiratory systems.[104] Routine imaging and hematologic tests in asymptomatic patients rarely identifies occult systemic disease that is associated with improved survival based on asymptomatic detection.[95] The presently available imaging modalities including computed tomography (CT), magnetic resonance imaging (MRI), PET, chest x-ray (CXR), and hematologic tests such as LDH lack both high sensitivity and specificity to make them routinely indicated. The reported true-positive rate of routine baseline CXR in asymptomatic patients ranges from 0 percent to 0.5 percent[105]; CT of the chest, abdomen, and pelvis 0.07 percent, and brain CT or MRI 0 percent.[95] Specificity is also low, and false-positive rates with these modalities range from 8 percent to 15 percent[104]; this leads to additional costly studies and possibly invasive procedures, as well as increased patient anxiety. Unfortunately, there are no data demonstrating improved survival rates if metastases are detected when clinically asymptomatic versus early symptomatic stage IV disease.[67,77,104] Current 2006 NCCN guidelines call for no additional workup in Stage 0 and 1A, optional CXR in stage 1B and II, optional CXR and LDH for stage III, and CXR and/or chest CT plus LDH for stage IV. Even for stage III and IV, further imaging with CT, MRI, or PET is recommended to be performed as clinically indicated, which emphasizes the importance of a thorough melanoma-focused review of systems and physical examination. In patients with a newly diagnosed stage III disease, a battery of tests may be indicated to obviate the need for surgery in the event that the patient has widespread asymptomatic metastatic disease.

Treatment of Primary Melanoma

SURGERY A general guideline algorithm for the management of cutaneous melanoma in 2006 is noted in Fig. 124-20. The standard of therapy for primary cutaneous melanoma is WLE. The purpose of the wider excision is to prevent local recurrence due to persistent disease by complete excision with histopathologically confirmed tumor-free margins. True local recurrence from inadequate excision is clinically significant in a small subset with the potential lethal consequence of preventable recurrence (Fig. 124-21). Current recommended clinical margins around the residual lesion or biopsy scar for melanoma in situ, non-LM pattern, is 0.5 to 1 cm; for melanoma < 1 mm Breslow depth a 1-cm margin; for melanoma 1 to 2 mm a 1- to 2-cm margin as anatomically possible; for melanoma > 2 mm a 2-cm margin (with pathologic confirmation of clear peripheral margins for all). Historically, surgical margins of 3 to 5 cm were taken, but several large, randomized controlled trials have failed to demonstrate a difference in survival rates or local recurrence rates between narrow (1 to 2 cm) versus wide (3 to 5 cm) margins.[106–112] Ultimately, each patient should be evaluated individually, taking into account current surgical guidelines as well as anatomic site (i.e., location near a vital structure), the possibility of primary closure versus need for skin graft, and the presence or lack of adverse prognostic factors from microstaging. Melanoma excision at special sites, such as the digits, soles, ears, vagina, or anus, also requires separate surgical and functional considerations. Still, the fundamental oncologic principle should be followed: tumor clearance first and most important, reconstruction second. A partial or complete amputation of the digit is still the preferred surgical treatment for subungual melanoma.

▲ **FIGURE 124-21** Potentially preventable deep local recurrence at both poles of previous local excision scar with satellite lesions, occurring approximately 4 years after narrow excision of a thin melanoma with 0.5-cm margins.

LENTIGO MALIGNA AND LENTIGO MALIGNA MELANOMA Histologic confirmation of negative margins is especially important for LM and LMM, sub-types of melanoma well known for their propensity for sub-clinical peripheral extension, as clinical margins are often poorly defined and obscured by background photodamage. The risk of a macular invasive desmoplastic component in the setting of the LMM pattern sub-type is also increased. Standard surgical recommendations of 0.5 cm margins for LM and 1 cm margin for LMM < 1 mm thick are often insufficient, and clear only about 50 percent of lesions. One study found that the average margin required to clear LM was 0.8 cm, and 1.5 cm to



clear 96 percent of LM lesions; the mean margin to clear LMM was 1.1 cm, 2.6 cm to clear 95 percent of LMM lesions.[113] Another reported that 97 percent of melanomas < 1.5 cm in diameter required 1.5-cm margin for complete excision whereas 95 percent of melanomas > 3 cm in diameter required 2.5-cm margin for complete excision.[114]

Recurrence rates for standard excision of LM range from 8 percent to 20 percent.[115] A variety of surgical techniques and methods of histologic evaluation have been advocated: standard excision with standard vertical sectioning (i.e., "bread loafing"); mapped staged excision with vertical sectioning cut at narrow intervals; Mohs micrographic surgery with frozen horizontal sectioning with or without immunostains; Mohs micrographic surgery with permanent horizontal sectioning; and mapped (i.e., "slow Mohs"), staged, geometric perimeter excisions with vertical sectioning of perimeter specimens (i.e., "square" technique).[116] The Mohs technique is desirable from a tissue-sparing perspective, but frozen section slides are extremely difficult to accurately interpret, even with the use of immunostains. Formalin fixed permanent section histology is the "gold standard" for histologic evaluation of surgical margin assessment of melanocytic lesions and are, in general, far superior to frozen sections.[117] Even with "slow Mohs," permanent processing and interpretation of horizontal sections is problematic in laboratories and for pathologists unaccustomed to this technique. The "square" technique provides high-quality material for complete margin evaluation in a format familiar to both the laboratory and the pathologist. Histologic margins require significant experience to evaluate, as there is a spectrum ranging from background benign junctional melanocytic hyperplasia to lesional trailing edge atypical junctional melanocytic hyperplasia.[118] One of the most frequently overdiagnosed proliferations are ones in which there are activated melanocytes. These cells are present very frequently in sun-damaged skin and exhibit a uniformity of appearance with either small round nuclei surrounded by a pale cytoplasm lying in the center of the "clear space" of a semilunar-shaped hyperchromatic nucleus with minimal cytoplasm lying along the basement membrane zone. This type of change can be found overlying most dermal nevi and angiofibromas in sun-exposed areas. An experienced pathologist is crucial.

Treatment of Regional Metastasis

MACROMETASTATIC NODAL DISEASE ***Complete Lymph Node Dissection.*** The current standard of therapy for microscopic or macroscopic melanoma in lymph nodes is complete lymph node dissection (CLND) of the involved regional basin. Uncontrolled nodal disease is a cause of melanoma-related morbidity with a significant negative impact on quality of life (see Fig. 124-18). The NCCN guidelines define an adequate lymphadenectomy as at least 10 lymph nodes in the groin, at least 15 lymph nodes in the axilla (levels I–II as clinically indicated), and at least 15 lymph nodes in the neck (levels I–V as clinically indicated). CLND is associated with significant morbidity, including wound infection, delayed wound healing, seroma, lymphedema, and nerve damage.[119]

CLND for regional metastatic melanoma is associated with long-term survival in a clinically significant proportion of patients. The best available evidence, although retrospective, reports overall melanoma-specific survival ranges at approximately 18 percent to 63 percent, and long-term (> 15 to 25 years) survival at approximately 35 percent, depending primarily on the number of nodes involved, palpable versus non-palpable nodes, ulceration status of the primary lesion, age, gender, and status of extracapsular spread.[120]

MICROMETASTATIC NODAL DISEASE ***Elective Lymph Node Dissection Versus Sentinel Lymph Node Biopsy.*** Elective lymph node dissection (ELND) is the removal of regional lymph nodes draining the site of a primary cutaneous melanoma in the absence of any palpable or clinically evident metastatic disease. Historically, before the advent of SLN biopsy, ELND was advocated for melanomas at higher risk of regional spread to eradicate subclinical micrometastases in a timely and potentially curative manner. Over the decades, multiple prospective randomized-controlled trials have all failed to demonstrate a significant improvement in survival from ELND versus clinical observation for melanoma as a whole.[121,122] Thus, there is no role for elective node lymph node dissection today, especially in light of its significant morbidity and the availability of SLN biopsy, which carries minimal morbidity.[123]

As mentioned previously (see Microscopic Metastases), the SLN biopsy procedure is a powerful staging tool that identifies micrometastatic nodal disease.[124] However, SLN cannot be classified as therapeutic yet. After positive SLN biopsy, 15 percent to 21 percent of patients have evidence of other non-SLN metastases found during CLND.[125] A positive SLN biopsy should be followed by a CLND. In addition, there is not yet definitive, high-level evidence that a positive SLN biopsy followed by immediate CLND improves overall survival in melanoma, compared to delayed CLND for clinically evident disease. Two large, prospective randomized trials designed to answer this question have been implemented and are ongoing. The Multicenter Selective Lymphadenectomy Trial enrolled 2001 patients with melanoma at least 1 mm Breslow depth or Clark level IV to receive WLE alone or WLE with SLN biopsy. Positive SLN biopsies led to immediate CLND; otherwise a delayed CLND was performed after development of clinical nodal metastases. Interim results indicate that 5-year survival was significantly higher for SLN-positive patients with immediate CLND than delayed CLND for clinical nodal recurrence (71 percent vs. 55 percent). For the WLE/SLN biopsy arm, 5-year survival was significantly higher for SLN-negative than SLN-positive patients (88 percent vs. 71 percent).[126] These interim results are promising and may be validated with maturation and complete reporting of full trial data.

The large, prospective, randomized, multi-institutional Sunbelt Melanoma Trial evaluated the role of reverse transcriptase-polymerase chain reaction (RT-PCR) for molecular staging with histologically negative SLNs. RT-PCR analysis was performed using four markers: tyrosinase, MART-1, MAGE3, and glycoprotein 100 and also was performed on peripheral-blood mononuclear cells. RT-PCR analysis on SLNs and peripheral-blood mononuclear cells provided no additional prognostic information beyond standard histopathologic (H&E plus immunohistochemical) analysis of SLNs, and there was no difference in disease-free, distant disease–free, or overall survival.[127] Thus, at present, RT-PCR for molecular staging of melanoma should not be used to direct therapy. Ongoing and future modifications and approaches in molecular staging of melanoma may hold promise.

ADJUVANT THERAPY ***Interferon-α 2b.*** Adjuvant therapy is additional treatment for patients surgically resected of clinical disease but at high risk for relapse (i.e., thick primaries > 4 mm or nodal

disease). High-dose interferon-α 2b (IFN-α 2b) is the only adjuvant therapy approved by the U.S. Food and Drug Administration (FDA) that has been shown to improve disease-free survival for stage IIB–III melanoma and improved overall survival in two multicenter cooperative group or intergroup trials, but not in pooled analysis. The high-dose regimen consists of 20 million units per square meter of body surface area per day, given intravenously 5 days a week for 4 weeks (induction phase), followed by 10 million units per square meter per day, given subcutaneously three times a week for 48 weeks (maintenance phase). Three large randomized controlled trials sponsored by the Eastern Cooperative Oncology Group (ECOG) have demonstrated higher disease-free survival (3 of 3 studies), and overall survival (2 of 3 studies) in stage IIB–III melanoma. ECOG 1684 demonstrated a significant increase in median disease-free survival (1 to 1.7 years) and overall survival (2.8 to 3.8 years) in the high-dose IFN arm compared to observation.[128] ECOG 1690 enrolled patients to either a high-dose IFN regimen, a low-dose regimen of 3 million units per day given subcutaneously three times a week for 2 years, or observation; there was a significant increase in disease-free survival but not overall survival for the high-dose regimen only.[129] ECOG 1694 enrolled patients to receive high-dose IFN or GMK vaccine (directed against a well-defined melanoma cell surface antigen GM2), and demonstrated a significant increase in both disease-free and overall survival. Interestingly, the appearance of autoantibodies or clinical manifestations of autoimmunity during treatment with IFN was assessed in a substudy of a larger, ongoing IFN randomized trial. Autoantibodies (antithyroid, anti-nuclear, anti-DNA, and anticardiolipin autoantibodies) and clinical manifestations of autoimmunity (vitiligo) were detected in 26 percent and were associated with statistically significant improvements in relapse-free survival and overall survival in these patients with melanoma undergoing adjuvant IFN.[130]

There are significant toxicities associated with the high-dose IFN regimen, the most frequent being flu-like symptoms in almost all patients (i.e., fatigue, anorexia, weight loss, myalgias, fever, nausea, headache). Other side effects include depression, hepatotoxicity (elevated transaminases), and myelosuppression. The toxicities require dose modification of IFN in most patients, but the majority are able to complete at least 80 percent of scheduled dosing, and are able to finish treatment if they make it through the first 3 months of therapy.[128] In addition, quality-of-life is improved, and patients seem to prefer IFN therapy to no treatment.[131,132] Consideration of potential benefits and risks of toxicities should be done on an individual basis.

Several studies have been conducted on low-dose IFN regimens to minimize toxicities associated with the high-dose regimen. Most have not been able to demonstrate significant increases in disease-free or overall survival. Two studies have shown improved disease-free but not overall survival in patients with medium-risk melanomas > 1.5 mm without nodal involvement.[133,134] It is possible to consider adjuvant therapy for melanoma with an intermediate risk of recurrence, but it is not generally done in current practice and should not be routinely done unless more studies demonstrate better overall survival.

Melanoma Vaccines. A number of autologous, allogeneic, and peptide vaccines have been studied widely in the management of melanoma but unfortunately without significant progress, as none is currently available as approved therapy. Vaccines are attractive, given elegant antigen-directed approaches and low toxicities. Vaccines attempt to stimulate a specific immune response against melanoma-associated antigens using autologous tumor cells or allogeneic melanoma cell lines, to which non-specific immunologic adjuvants such as bacille Calmette-Guérin or DETOX may be added. Newer strategies include the use of more specific targets such as heat shock proteins and T-cell defined tumor-associated antigens MART-1, glycoprotein 100, and tyrosinase, and the use of antigen-pulsed dendritic cells, antigen presenting cells, to activate T cells to these antigens.[135] None of the trials has reported a significant improvement in overall survival for patients who received vaccines.[136] However, one study's (Southwest Oncology Group 9035) subset analysis of patients who were positive for HLA-A2 and/or HLA-C3 demonstrated a significant 5-year overall survival benefit of 93 percent for patients in the vaccine group compared with 74 percent for patients in the observation group ($p = 0.009$).[137] A trial of autologous melanoma cells engineered to secrete granulocyte-macrophage colony-stimulating factor resulted in potent antitumor immune responses in patients with metastatic melanoma. Seventeen of 25 patients developed delayed-type hypersensitivity reactions to irradiated, dissociated, autologous, nontransduced tumor cells. There was one complete response, one partial, and one mixed response. Ten patients were reported as surviving in follow-up of 36 months.[138]

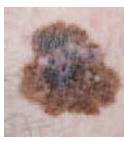
SATELLITE OR IN-TRANSIT METASTASES

Isolated Limb Perfusion. In general, regional in-transit or satellite disease should be surgically excised with clear margins whenever possible. However, if multiple lesions make surgery unreasonable, isolated limb perfusion (ILP) may be considered for locoregional disease limited to an extremity. ILP is a form of regional chemotherapy that delivers higher doses of chemotherapeutic agents with much less systemic toxicities. The complex, invasive technique involves perfusing an isolated extremity under hyperthermic conditions with cytotoxic agents, conventionally melphalan. In use for at least four decades, ILP with melphalan is an effective form of therapy, producing 80 percent overall responses rates and 50 percent complete responses (i.e., complete disappearance of all lesions).[139] ILP with tumor necrosis factor-α (TNF-α) in combination with melphalan has also garnered interest. However, the American College of Surgeons Oncology Group randomized phase III trial of ILP with melphalan, with or without TNF-α, was recently prematurely closed due to interim analysis showing comparable response rates for melphalan plus TNF-α and melphalan alone.[140]

The ILP procedure is associated with serious local morbidities, including significant tissue damage or compartment syndrome. Elderly age and serious medical co-morbidities are generally considered exclusion criteria. Isolated limb infusion (ILI) is a newer, simpler, less invasive technique. Early studies of ILI with melphalan and actinomycin D demonstrate comparable efficacy to ILP with melphalan.[141] ILI may be considered for patients ineligible for ILP. Both ILP and ILI are available only at a few specialized centers.

Treatment of Distant and/or Disseminated Metastasis

The treatment of stage IV melanoma must take into account that the average survival is 6 to 8 months and that no systemic therapies have been shown to significantly increase survival in randomized



controlled trials.[87] Goals of treatment should be increasing length of survival and palliation of symptoms. The option of observation and conservative treatment is reasonable, especially in the asymptomatic, elderly, or those with serious comorbidities. Surgical excision of isolated visceral metastases (i.e., metastasectomy) demonstrated to be stable over a 3- to 6-month period before excision may be performed but long-term survival is the exception. Surgical excision of skin/subcutis or distant lymph node metastases may result in better locoregional control and decreased morbidity.[142] Surgery may also be palliative—for example, to relieve obstruction from gastrointestinal metastases. Melanoma is not known to be very radiosensitive, but radiotherapy is used for brain metastases. Palliative radiation may be indicated for spinal cord compression and painful bone metastases.

SYSTEMIC THERAPIES ***Chemotherapy.*** The alkylating agent dacarbazine (DTIC) is the only FDA-approved chemotherapy (for > 25 years) for metastatic melanoma and is considered to have the greatest efficacy as a single agent. Response rates are in the 10 percent to 20 percent range, with median response duration 4 to 6 months.[143] There is no difference in terms of response rates and duration of response between the various dosing schedules used. The major side effects are nausea and vomiting. Temozolomide (TMZ) is an alkylating agent with the same active metabolite as DTIC, but it is able to cross the blood-brain barrier and can be absorbed orally. TMZ has been shown in a randomized phase III study to have efficacy equal to DTIC.[144] There has been interest for TMZ as a treatment of melanoma metastatic to the brain. An oral regimen of TMZ and thalidomide for brain metastases in conjunction with radiation is under investigation.[145] Still, TMZ has not received FDA approval. Higher response rates are seen with combination therapies, typically of dacarbazine along with other cytotoxic agents such as cisplatin, vinblastine (CVD regimen), carmustine, or tamoxifen. Still, no randomized controlled trial has shown any combination to be superior to DTIC alone.[87]

Immunotherapy. High-dose bolus interleukin 2 (IL-2) is the only FDA-approved (recently in 1998) immunologic treatment of metastatic melanoma that may produce durable complete responses. It has been shown as a single agent to produce a 16 percent overall response rate but with a durable response in up to 5 percent to 8 percent of patients. The median response duration of 9 months; 28 percent of the responders have remained progression-free at a median follow-up of 62 months.[146] Furthermore, no patient responding longer than 30 months has relapsed, suggesting the possibility of a "cure." However, high-dose IL-2 is associated with significant toxicity, including hypotension [most common (64 percent)], capillary leak syndrome, arrhythmia (particularly supraventricular tachycardia), respiratory distress, transient renal insufficiency, and infections/sepsis. Its use is limited to specialized programs with experienced clinicians.

Combining IL-2 with immunologically active cells (i.e., adoptive immunotherapy) is also being studied. The adoptive transfer of stimulated immune effector cells to generate an antitumor effect has been tried with lymphokine activated killer cells and tumor-infiltrating lymphocytes. Results of clinical trials with lymphokine activated killer cells have been uniformly disappointing, but IL-2 with tumor-infiltrating lymphocytes has shown potential promise in small clinical trials.[147]

Biochemotherapy. Ongoing therapeutic investigations have focused on immunotherapies, especially vaccine-based therapies, in combination with other available systemic agents. Various biochemotherapy regimens of dacarbazine, other chemotherapeutic agents, and IFN, vaccines, or IL-2 are being tested in numerous trials, but again, have not shown survival benefit compared to chemotherapy or immunotherapy alone.[87]As might be expected, these combination regimens are more toxic than the individual components alone.

Novel Therapies. Impairment of apoptosis, or programmed cell death, contributes to tumorigenesis and tumor resistance to chemotherapy. The anti-apoptotic protein B-cell lymphoma 2 (Bcl-2) has been implicated in the intrinsic resistance of melanoma to chemotherapy. Oblimersen sodium (Genasense) is a novel antisense Bcl-2 oligonucleotide that selectively targets Bcl-2 messenger RNA, leading to its degradation and decreased Bcl-2 levels. Oblimersen sodium enhances apoptosis by itself and in conjunction with other cytotoxic agents. In a large randomized phase III trial, oblimersen plus dacarbazine has shown potential promise.[148]

B-raf mutations have been found in two-thirds of melanomas.[26] Sorafenib is a novel RAF inhibitor that inhibits B-raf and C-raf, and is orally available. Early studies have demonstrated clinical response in metastatic melanoma to Sorafenib monotherapy, and it was well tolerated. A phase III trial is in the process of being coordinated by ECOG; 800 patients will be randomized to receive carboplatin and paclitaxel with or without Sorafenib.

Prognostic modeling with molecular profiling represents a future tool to assist in improved selection of surgical and systemic therapies. Unfortunately, no satisfactory curative adjuvant or systemic therapy exists today for patients with stage IV metastatic disease.

Follow-Up

Patients with melanoma are at risk for local, regional, and distant recurrence, with the level of risk dependent on the stage at initial diagnosis and workup. Follow-up visits are an opportunity to review how to perform monthly self-skin and lymph node examinations, address any psychosocial emotional distress issues, obtain a melanoma-focused review of systems, and provide continuing patient education regarding early detection signs and symptoms and sun protection/prevention strategies. Regular follow-up is indicated for all patients with melanoma. Current NCCN and national melanoma center guidelines call for at least annual follow-up visits for life, with follow-up intervals generally ranging from every 3 to 6 months for 1 to 3 years after diagnosis and annually thereafter, depending primarily on stage of disease. Patients with other risk factors, such as a positive family history of melanoma, numerous nevi, a mutation in p16 or BRAF, or difficulty with self-examination, may require more frequent follow-up. A referral to a genetics counselor is warranted if there is a strong family history of melanoma.

The follow-up visit should consist of a thorough complete skin examination for additional primary lesions and cutaneous/subcutaneous metastases, particularly in the regional distribution of the primary, palpation of lymph nodes with particular attention to the regional nodal basin, and thorough history-taking. The review of systems is the foundation for detecting symptomatology possibly attributable to melanoma, and directs additional testing or imaging. The yield and value of routine imaging to re-stage asymptomatic patients as part of standard melanoma follow-up are low and, thus, imaging and hematologic tests are

based on any suspicious findings from a good history and physical examination.

PREVENTION

Public awareness and knowledge of melanoma and UV exposure is improving, but still a substantial gap exists between knowledge and behavior. Primary prevention strategy should focus on safe sun exposure, including limited UV exposure and sunburn prevention, especially in childhood and adolescence when the risk is greatest. Avoidance of peak sunlight hours and use of wide-brimmed hats, clothing, and sunscreen are recommended. In addition, early detection by regular self-skin examinations, skin awareness, and knowledge of the early signs and symptoms of melanomas should also be emphasized. The goal of secondary prevention is early diagnosis, which greatly reduces melanoma-related morbidity and mortality.

SECTION 23

TUMORS AND HYPERPLASIAS OF THE DERMIS AND SUBCUTANEOUS FAT

CHAPTER 125

Malignant Fibrous Tumors of the Dermis

Jennifer Z. Cooper
Marc D. Brown

Malignant fibrous tumors of the dermis represent one end of a spectrum[1] that begins with benign fibrous tumors and fibroplasias. Fibrous lesions are often composed predominantly of stroma and only in certain high-grade sarcomas is the neoplastic nature of the lesion obvious.[2] Identification of defined chromosomal abnormalities suggests a neoplastic status for some fibrous lesions traditionally regarded as reactive. This chapter focuses on malignant lesions and Chap. 64 discusses benign fibroplasias and tumors.

DERMATOFIBROSARCOMA PROTUBERANS

Epidemiology

Dermatofibrosarcoma protuberans (DFSP) is a rare, locally aggressive dermal and subcutaneous mesenchymal neoplasm that typically occurs during the third and fourth decades of life, although it has been reported in patients from infancy to the ninth decade. DFSP accounts for less than 0.1 percent of all malignant neoplasms and represents 2 percent to 6 percent of all soft-tissue sarcomas. There does not seem to be a racial predilection for the tumor, however, the pigmented variant (Bednar's tumor) is more common in black patients. There seems to be a fairly equal distribution between male and female patients.[3]

Etiology and Pathogenesis

The histogenesis of DFSP is uncertain: fibrohistiocytic, purely fibroblastic, and neural-related differentiation have all been hypothesized. A very sensitive, although non-specific, marker for DFSP is CD34. A distinctive cell population within normal nerves has been shown to express CD34, consistent with a possible neural-related histogenesis of DFSP. CD34 can help distinguish between DFSP and scar tissue in re-excision specimens.

At the molecular level, DFSP exhibits the reciprocal translocation t(17;22)(q22;q13), producing a fusion of the collagen type I α 1 gene and the platelet-derived growth factor B-chain gene. Current techniques permit sensitive and specific detection of these fusion transcripts in paraffin-embedded DFSP tumor specimens by reverse transcription polymerase chain reaction. Both fibrosarcomatous transformation of DFSP and some cases of superficial fibrosarcoma have been shown to harbor these fusion transcripts, suggesting a close affinity between DFSP and fibrosarcoma.

Clinical Findings

HISTORY DFSP is a slow-growing lesion that often presents on the trunk and proximal extremities of patients. Due to its indolent onset, the patient may present for evaluation when the tumor is several centimeters in size (Fig. 125-1). The tumor is often misdiagnosed as a simple scar or cyst. It often grows to several centimeters in diameter and may form large, infiltrative tumors. In a small portion of patients, previous trauma at the site has been reported. DFSP has also been described as arising in scars, including surgical, burn, and vaccination sites.

CUTANEOUS LESIONS The clinical morphology of DFSP is variable. The most common presentation is a firm, indurated plaque, often skin-colored with red-brown exophytic nodules (see Fig. 125-1A). It also can present as a nonprotuberant, atrophic, violaceous lesion resembling morphea, sclerosing basal cell carcinoma, anetoderma, or scar (Fig.

MALIGNANT FIBROUS DERMAL TUMORS AT A GLANCE

- A group of uncommon and rare cutaneous tumors with varying degrees of malignant potential.
- Includes dermatofibrosarcoma protuberans, atypical fibroxanthoma, malignant fibrous histiocytoma, fibrosarcoma, and epithelioid sarcoma.
- Diagnosis is made by biopsy.
- Dermatofibrosarcoma protuberans is a locally aggressive tumor with a high rate of local recurrence with rare metastases.
- Atypical fibroxanthoma is an intermediate-grade neoplasm that usually arises on sun-damaged skin in the eighth decade.
- Malignant fibrous histiocytoma represents a morphologic pattern that a large number of poorly differentiated neoplasms share.
- Epithelioid sarcoma is a rare tumor that classically presents on the hands and fingers of young males, which can mimic nonneoplastic inflammatory lesions.

▲ **FIGURE 125-1** **A.** Dermatofibrosarcoma protuberans presenting as reddish brown confluent flat nodules. **B.** Dermatofibrosarcoma protuberans showing fibroblastic spindle cells that are arranged in interlacing fascicles. These intersect and bend at acute angles, producing a starburst (storiform) pattern.

125-2). Large nodular tumors may occur. The epidermis may be atrophic and focal ulceration may occur. The most common site of DFSP is the trunk, followed by the extremities. Approximately 15 percent of DFSP occurs on the head and neck.

LABORATORY TESTS ***Histopathology.*** DFSP is diagnosed with a skin biopsy. A deeper wedge biopsy may be required to diagnose the atrophic variant. Histologically, DFSP is a poorly circumscribed dermal proliferation of monomorphous, slender or slightly plump spindle cells with little pleomorphism arranged in a storiform pattern (see Fig. 125-1B). The proliferation commonly infiltrates the subcutaneous fat, isolating adipocytes to form lucencies ("honeycomb" or "Swiss cheese" pattern). In contrast to dermatofibroma, the tumor is much more cellular and usually does not have mature collagen interspersed between fascicles of spindle cells.

Variable histologic patterns described include myxoid, neuroid, fibrosarcomatous, myxoid, and granular cell types. The tumor may be relatively monomorphous or show combinations of various patterns within the original tumor or in the recurrences. Some lesions show overlap between giant cell fibroblastoma and DFSP. The fibrosarcomatous variant has basic features of DFSP but focal areas in which the cells exhibit a high grade of atypia and are arranged in long fascicles in a herringbone (fibrosarcoma-like) pattern. This transformation appears to be related to mutations in the p53 pathway. Several series indicate an increased biologic aggressiveness of this type compared with ordinary DFSP In a series from Memorial Sloan-Kettering Cancer Center, patients with this histologic variant had a 28 percent 5-year recurrence-free survival, as compared to 81 percent of those with classic DFSP. However, in a series from the Cleveland Clinic, patients with sarcomas arising in DFSP did not have an increased risk of distant metastasis within a 5-year follow-up period, providing that adequate surgical excision with wide margins was performed. It is estimated that there is a 5 percent transformation rate from DFSP to conventional fibrosarcoma. The true impact of fibrosarcomatous changes seen within a DFSP remains uncertain.

▲ **FIGURE 125-2** Atrophic variant of dermatofibrosarcoma protuberans.

Special Tests. Immunohistochemical staining with CD34 is useful to distinguish DFSP from dermatofibroma, which stains positively for factor XIIIa. Other markers, such as CD44, a membrane glycoprotein, and hyaluronate, a component of the extra-cellular matrix, may serve as markers to better distinguish DFSP from dermatofibroma as well. Apolipoprotein D also may have future application as a marker for DFSP.

Differential Diagnosis (Box 125-1)

Complications

DFSP is a low-grade malignant tumor, often infiltrating diffusely through the dermis and into the subcutaneous fat but seldom metastasizing. Increased age, high mitotic index, and increased cellularity are predictors of poor clinical outcome. Approximately 30 percent to 50 percent of DFSPs recur locally after simple excision, so it is generally recommended that a wide excision with 1- to 3-cm margins to the fascia or periosteum be performed (see Treatment).

Prognosis and Clinical Course

Local recurrences even after wide excision are common, although, much

greater success seems to be had with using the Mohs technique for tumor extirpation. Metastases of DFSP are extremely rare, usually occurring in the setting of multiply recurrent tumors. Metastases to the lung are most common, with nodal disease the next most common site of spread. Metastatic disease portends a poor prognosis. It has been suggested that tumors with fibrosarcomatous change may have a higher chance of recurrence or metastases.

Treatment

Surgical removal with clear margins is the goal with DFSP. With standard excision, margins of 1 to 3 cm may be necessary to achieve clear margins. Risk of local recurrence decreases with increasing surgical margins. Pathologic examination of margins during surgery is helpful in delineating the extent of the tumor. Multiple case series have shown Mohs surgery to be an extremely effective method of resection of DFSP, with an extremely low rate of local recurrence.[4,5] As a result, Mohs micrographic surgery represents the preferred surgical approach of many practitioners. Adjuvant radiation therapy may help decrease the local recurrence rate. The use of imatinib, a chemotherapeutic agent that targets the molecular translocation distinctive to this tumor, has shown promise in the setting of localized advanced disease (i.e., unresectable tumors) or metastatic disease.[6] Imatinib may also emerge in the future as an adjunct to surgery.

GIANT CELL FIBROBLASTOMA

Giant cell fibroblastoma, a rare neoplasm, now known to be a juvenile variant of DFSP,[7] typically presents as a dermal or subcutaneous mass, which most frequently involves the trunk, thigh, or inguinal region. It presents much earlier in life, often within the first decade, although occurrences in adults have been reported. Histologically, this tumor has dense connective tissue with a paucity of fibroblasts and occasional wreath-like giant cells. There are also scattered mast cells present. These tumors resemble DFSP with their pattern of tumor infiltration. The tumor cells infiltrate the subcutis and surround adnexal structures. Most characteristically, the stroma displays prominent cracking artifact, with the formation of pseudovascular spaces lined by a discontinuous layer of enlarged, multinucleated tumor giant cells with coarse nuclear chromatin and scalloped nuclear borders. Immunohistochemically, these tumors stain positive for CD34 and occasionally α1 antichymotrypsin. They stain negative for factor VIII, von Willebrand's factor, CD31, actin, desmin, epithelial membrane antigen, and S100. As noted previously, this tumor shares the identical translocation with DFSP—(t17;22), collagen type I α 1 gene–platelet-derived growth factor B-chain gene.

The clinical behavior of giant cell fibroblastoma is much like that of DFSP. It shows local aggressive behavior, frequent local recurrences (up to 50 percent), and rare metastasis. Treatment is the same as for DFSP.

ATYPICAL FIBROXANTHOMA

Epidemiology

Atypical fibroxanthoma (AFX) is a relatively common rapidly growing neoplasm of intermediate malignant potential. It occurs mainly on sun-exposed skin (face, neck, and hands) of elderly individuals. The male-to-female ratio is essentially equal. AFX has been reported in the second to tenth decade, with a mean age of approximately 69 years.

Etiology and Pathogenesis

The anatomic distribution and the presence of cyclobutane pyrimidine dimers support a pathogenic role for ultraviolet radiation in the development of AFX. Tumors may occur 10 to 15 years after local ionizing irradiation.

Clinical Findings

HISTORY The patient may report a lesion on sun-damaged skin of relatively rapid onset. The lesion usually presents as a solitary, often dome-shaped nodule, which may be eroded or ulcerated. The size of presentation is usually less than 3 cm in diameter.

CUTANEOUS LESIONS AFX appears as an asymptomatic, solitary papule or nodule (Fig. 125-3) often resembling a squamous cell carcinoma, basal cell carcinoma, or even a necrotic pyogenic granuloma. It is often friable, eroded, or ulcerated. The AFX is typically less than 2 cm in size and is most commonly seen on the actinically damaged skin of older patients, especially ears, cheeks, nose, and scalp. The background skin is often sun damaged. AFX may be found in the setting of other non-melanoma cutaneous malignancy.

LABORATORY TESTS ***Histopathology.*** Diagnosis is by skin biopsy. Specimens often show partially exophytic tumors with ulceration of the overlying epidermis. A grenz zone may be present, but usually the tumor abuts onto the dermal-epider-

mal junction. A poorly circumscribed hypercellular tumor may extend deeply into the reticular dermis or subcutis. It consists of spindle cells in a collagenous or occasionally myxoid stroma admixed with multinucleated giant cells and epithelioid cells (see Fig. 125-3B). The neoplastic cells display pronounced atypia, with bizarre, large, round or ovoid hyperchromatic nuclei with numerous mitotic figures (some of them atypical); large, prominent eosinophilic nucleoli; and abundant, occasionally vacuolated cytoplasm. Some cells may contain fine droplets of lipid, demonstrable by oil red O stains on frozen tissue. The spindle cell sub-type of AFX occurs in the same clinical setting as an ulcerated tumor and is characterized by a monomorphous proliferation of spindle cells with very little pleomorphism.

Special Tests. Immunohistochemically, AFX has variable profiles, but cells usually express vimentin and histiocytic markers such as α_1-antitrypsin, α_1-antichymotrypsin, HAM-56 antigen, and CD68. A few express factor XIIIa. CD99 has been proposed to be a relatively sensitive marker (73 percent of cases) and, in context, a specific marker for these tumors. Expression of S100A6 also appears to be a sensitive marker for AFX. MIB1 (Ki-67) may be another useful marker in this highly proliferative tumor. LN2 (CD74) has been suggested to represent a marker of more aggressive behavior in this tumor.

Differential Diagnosis

See Box 125-1.

Prognosis and Clinical Course

AFX has long been regarded as a neoplasm with extremely low metastatic potential. There have been several reports of metastatic disease, some resulting in death.[7] Many consider AFX to be a superficial variant of malignant fibrous histiocytoma (MFH), which has much more ominous behavior. Overlap between these two tumors may account for the AFX cases with reported metastases. AFX is often found in the setting of diffuse actinic damage and other non-melanoma skin cancer, so close follow-up after complete tumor extirpation is prudent.

Treatment

Treatment for AFX is surgical. Studies have suggested that Mohs micrographic surgery provides a lower rate of recurrence than wide local excision. Excision should be to the level of the deep subcutaneous tissue. Adjuvant treatment with radiation may be considered for tumors with particularly aggressive onset. It also may be considered in the setting of positive LN2 (CD74) staining of the tumor.

Prevention

Protection from ultraviolet damage may serve as one measure of prevention of this tumor.

MALIGNANT FIBROUS HISTIOCYTOMA

Epidemiology

In the recent past, MFH has been considered to be the most common malignant soft tissue tumor. Reclassification of soft tissue sarcomas by the World Health Organization in 2002 has mandated identification of cell line origin in the classification of tumors.[8] Thus, MFH as previously considered, is merely a morphologic pattern rather than a defined pathologic entity. In most cases, careful immunohistochemical and ultrastructural examination permits probable or definite classification into defined histogenetic sub-types of sarcoma. Currently, MFH remains in the soft-tissue sarcoma nomenclature as a synonym for undifferentiated pleomorphic sarcoma, not otherwise specified. In future reclassification schema, the term *MFH* may become obsolete.

Keeping the more current classification system in mind, two tumors are more likely to have a cutaneous presentation. The undifferentiated pleomorphic sarcoma, (former pleomorphic and storiform MFH) and the myxofibrosarcoma (former myxoid MFH). Both of these tumors tend to occur on the limbs of elderly patients. Myxofibrosarcoma now represents one of the most common soft tissue sarcoma of the elderly.

Etiology and Pathogenesis

The pathogenesis of soft-tissue sarcomas has not been well defined. Depending on the cell of origin, various genetic, physical, chemical, and viral etiologies have been suggested.

Clinical Findings

HISTORY Both the undifferentiated pleomorphic sarcoma and the myxofibrosarcoma may present as a subcutaneous mass, most commonly on the limb (or limb girdle in the case of myxofibrosarcoma). Both can be progressively enlarging.

CUTANEOUS LESIONS When presenting as cutaneous lesions, these tumors are usually skin-colored subcutaneous nodules, varying from elastic to firm in texture. At times, growth of the tumor may be rapid. It is usually solitary but can be multinodular and may be 5 to 10 cm at the time of initial diagnosis. The more superficial MFH tumors are usually smaller. The extremities are the most common site of involvement, with the lower extremities affected more commonly than the upper extremities. Any area of the body may be involved, and approximately 10 percent to 15 percent of MFH tumors are on the head and neck region.

Laboratory Tests

HISTOPATHOLOGY The most common appearance is of spindle cells in a storiform pattern. The stroma may be finely fibrillary, myxoid, or densely collagenous. Bizarre epithelioid and giant cells may be present and may contain small amounts of lipid. Many mitotic figures, bizarre giant cells, and necrosis are common. Ultrastructurally, the neoplastic cells have features consistent with fibroblastic, myofibroblastic, and histiocytic differentiation.

SPECIAL TESTS Immunohistochemistry using a broad antibody panel is required to rule out metastatic carcinoma, lymphoma, leiomyosarcoma, melanoma, and similar lesions.

Differential Diagnosis

See Box 125-1.

Prognosis and Clinical Course

Up to 50 percent of patients presenting with an undifferentiated pleomorphic sarcoma may have distant metastases (lung most likely). Recurrence is common, and may result in up to a 30 percent to 35 percent metastatic rate. Low-grade variants, including superficial cutaneous tumors are much less likely to metastasize.

Treatment

Complete surgical resection at presentation offers the best chance for survival. Radiation therapy plays an important role

in combination with surgery for better local control, particularly in high-grade lesions and in patients with positive surgical margins after wide complete gross excision. Special note should be made of angiomatoid fibrous histiocytoma (AFH) that occurs primarily in children and young adults. AFH was mistakenly classified as a sub-type of MFH/AFH. Based on AFH's benign behavior and rare ability to metastasize, it is now considered to be a benign tumor of uncertain differentiation. This tumor has four key morphologic features: (1) multinodular proliferation of eosinophilic, histiocytoid, or myoid cells; (2) pseudoangiomatoid spaces; (3) thick fibrous pseudocapsule; and (4) pericapsular lymphoplasmacytic infiltrate. Immunohistochemical studies demonstrate scattered desmin, variable epithelial membrane antigen, and variable $CD68^+$ cells. Laminin and collagen IV are expressed in this tumor. Ultrastructure demonstrates a pericytic differentiation. The use of reverse transcriptase-polymerase chain reaction for the detection of fusion transcripts (FUS-ATF1 and EWSR1-ATF1) may be helpful in the distinction between AFH and other soft tissue tumors. Some AFH tumors have 11q24 deletions. These tumors require local excision and have an indolent behavior. Recurrence occurs in 2 percent to 10 percent of cases and rarely have metastases been reported (less than 1 percent of cases).

EPITHELIOID SARCOMA

Epidemiology

Epithelioid sarcoma (ES), an extremely rare, aggressive sarcoma, occurs most often on the hands and fingers of young males.[9] Proximally located tumors (e.g., groin, thigh, vulva, and axilla) have a much worse prognosis.

Etiology and Pathogenesis

The etiology is obscure; possibly trauma plays some role. Inactivation of the SMARCB1/INI1 tumor suppressor gene was identified in a series of 6 of 11 ES, which may in part explain its pathogenesis or propensity for progression.

Clinical Findings

HISTORY The patient may present with subcutaneous nodules on the hand or fingers. Often, there is a delay in diagnosis due to the rare nature of this tumor and the resemblance to more common inflammatory skin lesions, such as granuloma annulare.

▲ **FIGURE 125-4** Epithelioid sarcoma typically occurring over the wrist. Note ulceration and granuloma-like border.

CUTANEOUS LESIONS ES usually presents as a firm dermal or subcutaneous nodule, sometimes with ulceration or sinus formation (Fig. 125-4). Linear subcutaneous nodules due to progressive multifocal spread along tendons, nerves, and fascia may give a sporotrichoid appearance.

LABORATORY TESTS Diagnosis is by biopsy, dermal lesions may be biopsied by punch or wedge biopsy. Most lesions occur in fascia, tendon, or subcutaneous septa; approximately 25 percent arise in the dermis. The tumor usually presents as a multinodular mass composed of epithelioid cells with abundant eosinophilic, often vacuolated, cytoplasm admixed with spindle cells in a collagenous and myxoid stroma. Characteristically, there is central necrosis with a surrounding palisade of tumor cells.

SPECIAL TESTS Tumor cells express vimentin and epithelial markers. In a large series, epithelial membrane antigen was present in 96 percent of patients, and muscle-specific actin and CD34 were noted in 41 percent and 52 percent of the patients, respectively.

Differential Diagnosis

See Box 125-1.

Prognosis and Clinical Course

The tumor has local recurrence rates of up to 50 percent and nodal or hematogenous metastasis in 40 percent of patients. The lung and pleura are the most common sites of metastatic disease.

Because the classic location on distal extremities often discourages early deep biopsy, and because epithelioid sarcoma may closely mimic various non-neoplastic lesions histologically such as granuloma annulare, it often evades diagnosis at an early, localized stage.

Treatment

Radical excision traditionally has been the treatment of choice, but recurrences occur even with amputation. Conservative (limb-sparing) surgery combined with preoperative or postoperative radiation therapy has been tried, with results comparable with those reported with radical amputation. Chemotherapeutic regimens have not been successful. A high mitotic rate, large areas of necrosis, vascular invasion, and size greater than 5 cm are associated with worse prognosis.

CHAPTER 126

Vascular Tumors

Tara Miller
Ilona J. Frieden

Vascular anomalies are common birthmarks.[1] Their classification has often been problematic, with contradictory and confusing descriptive nomenclature. A classification system first proposed by Mulliken and Glowacki was revised in 1996 by the International Society for the Study of Vascular Anomalies based on clinical, radiologic, and hemodynamic characteristics, into vascular malformations and vascular tumors.[2] Vascular malformations (see Chap. 173) are errors of morphogenesis whereas hemangiomas and other vascular tumors grow by cellular proliferation.

There are several types of vascular tumors, most of which occur in childhood. These tumors have also had confusing nosology,[3] with descriptive but imprecise terminology such as *strawberry*, *capillary*, and *cavernous*. Several types of hemangiomas have been described (infantile, rapidly involuting congenital, lobular capillary, etc.), so whenever possible, *hemangioma* should not be used as a stand-alone noun but rather qualified by an adjective based on the specific condition.

INFANTILE HEMANGIOMAS

Epidemiology

Infantile hemangiomas (IH) are the most common benign tumors of childhood, occurring in up to 10 percent of children by 1 year of age.[4] In contrast to other types of hemangiomas and vascular malformations, IH have a characteristic proliferative phase followed by a slower involution phase. They are more common in females (2–3:1 ratio) and in premature infants, especially those weighing less than 1500 grams.[5] Other risk factors are Caucasian race and multiple gestation pregnancy.

Etiology and Pathogenesis

IH are primarily composed of endothelial cells but also contain fibroblasts, pericytes, interstitial cells, and mast cells. Although the precise pathophysiologic mechanisms of the growth and involution of endothelial cells remains unknown, several recent discoveries have advanced the understanding of IH.[6] Glucose-transporter-1 (GLUT-1) has been identified as an immunohistochemical marker expressed in IH, regardless of stage, and in the microvasculature of the placenta.[7,8] GLUT-1 is not expressed in other vascular tumors and malformations, thus making it a specific and useful marker for IH. IH and the placenta share other vascular antigens such as FcγRII, Lewis Y antigen, and Merosin; the two also have similar gene expression profiles based on DNA-based microarrays.[9] Both "intrinsic" and "extrinsic" hypotheses exist to explain these findings: A somatic mutation may cause fetal vascular precursor cells (angioblasts) to improperly differentiate toward a placental microvascular phenotype or, alternatively, hemangiomas may originate from the placental vasculature. IH lack placental trophoblastic markers, suggesting that embolization of the placenta itself (as distinct from placental microvasculature) is not the source of IH.[10]

Proliferating IH express CD31 and CD34, known markers for endothelial cells, in addition to CD133, expressed in primitive cell populations.[11] This coexpression suggests that endothelial progenitor cells are involved in the pathogenesis of IH. However, IH also express myeloid markers CD14, CD15, CD32, and CD83 suggesting that these endothelial cells are distinct from those of normal vasculature.[12] While most IH are negative for lymphatic markers such as Prox-1, podoplanin, and D2-40, some IH express the lymphatic marker LYVE-1.[13] This immunophenotype is similar to the immature endothelial cells in the cardinal vein, which can differentiate into either lymphatic or blood vessels.[14] Expression of CD31, CD34, CD133, and LYVE-1 is markedly reduced or absent in other vascular tumors and malformations and during the involuting phase of IH. The concept of hemangioma cells being immature and incompletely differentiated could help explain their rapid growth during the first few months of life, followed by their eventual self-destruction via apoptosis.

Clinical Findings

HISTORY The clinical history is one of the most important keys to diagnosing an IH (Table 126-1).[21] Absence at birth or presence as a premonitory mark, usually an area of pallor, telangiectasias, or duskiness is characteristic, whereas a fully formed soft-tissue mass at the time of birth is most likely not an IH, but another vascular anomaly or other disease process.

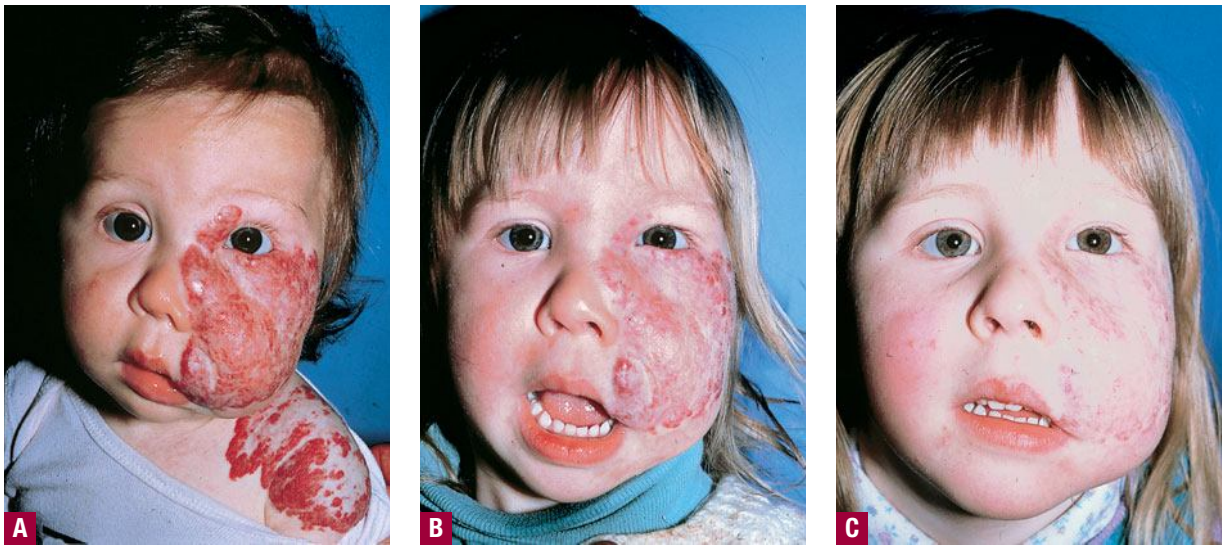
CUTANEOUS LESIONS ***Growth Characteristics.*** Though IH are not present at birth as fully formed tumors, they almost al-

INFANTILE HEMANGIOMAS AT A GLANCE

- Infantile hemangiomas are the most common tumor of infancy.
- Hemangiomas in high-risk anatomic sites are likely to require further work-up and, often, intervention.
- Segmental hemangiomas have a greater risk for morbidity than localized hemangiomas.
- Kasabach-Merritt syndrome is not due to infantile hemangioma.

TABLE 126-1
History

- Birth history
  - Was the child premature?
  - Part of a multiple gestational birth?
  - Complications during the pregnancy or delivery?
- Overall health and past medical history
  - Is the child feeding well and gaining weight appropriately?
  - Have there been any hospitalizations or major illnesses?
- History of "birthmark"
  - Was it visible at the time of birth?
  - Has it changed since birth?
  - Growth: Is it growing proportionately or disproportionately with child's somatic growth? Is it still growing, stable, or shrinking in size? (Serial photographs are often helpful.)
  - Any complications such as pain, bleeding, or ulceration?
  - Any prior treatments?
- Family history
  - Is there a family history of hemangiomas or other vascular birthmarks?



▲ **FIGURE 126-1** Natural history of segmental infantile hemangioma. Note the plaque-like, geographic configuration. **A.** Age 11 months, peak of proliferating phase. **B.** Age 2 years, involuting phase, apoptosis is maximal. **C.** Age 4 years, some further involution expected.

ways become apparent within the first month of life. The exception is deep hemangiomas, which are noted on average 1 month later than more superficial ones. The period of most rapid growth typically occurs within the first 5 months of life but can continue up to 1 year of age and in very large hemangiomas up to 18 months. This is followed by a slower involution phase which is more variable in length, lasting for months to years (Fig. 126-1).[22] Smaller hemangiomas typically involute sooner than very large ones, but there are exceptions. Most IH complete their course by the age of 7 to 10 years. Some children have normal skin after involution whereas the remainder has telangiectasias, atrophy, fibrofatty residuum, or scarring.

***Classification*[23].** Hemangiomas which involve the upper dermis (so-called *superficial hemangiomas*) have a bright red color; whereas those with deep dermal and subcutaneous location are skin color to blue in color. Those involving both superficial and deeper skin structures, so-called *mixed* hemangiomas, have both features. In addition to this clinical appearance, infantile hemangiomas can be classified as localized, segmental, or indeterminate.[24,25] Localized hemangiomas exhibit clear spatial containment as if arising from one central focus (Fig. 126-2). Segmental hemangiomas (similar to other segmental dermatologic disease such as vitiligo and neurofibromatosis) correspond to a portion of a developmental segment or broad anatomic territory (Fig. 126-3). They are often plaque-like in nature with a linear or geographic configuration. Those hemangiomas not clearly identifiable as localized or segmental are termed *indeterminate* (see Fig. 126-3). The patterns of facial segmental IH have been found to correspond to neural-crest derived facial prominences, and a new map for them has recently been proposed.[23] Multifocal hemangiomas are usually multiple localized hemangiomas. Though the exact number is somewhat arbitrary, more than five hemangiomas confers a risk of extra-cutaneous hemangiomas.

Classification of hemangiomas by subtype not only facilitates communication but also helps predict risk of complications and need for treatment. A prospective study of 1058 children with IH showed that segmental hemangiomas are 11 times more likely to experience complications and eight times more likely to receive treatment than localized hemangiomas even when controlled for size.[26]

Atypical Presentations. Atypical presentations of IH include deep hemangiomas and telangiectatic hemangiomas. Deep IH proliferate in the lower dermis and subcutaneous tissue without penetration of the papillary dermis (Fig. 126-4). They present as a localized, firm, rubbery subcutaneous mass that can be slightly raised with a bluish color or with telangiectasias involving the overlying skin, or they may be deep enough that the overlying skin is completely flat and of normal hue. If there is involvement of the papillary dermis, the cutaneous surface is often bright red and thus classified as a superficial and deep IH. Telangiectatic hemangiomas are flat or slightly elevated and deep red with an array of superficial dilated capillaries radiating over the surface (Fig. 126-5). These are virtually identical to premonitory marks, but for unknown reasons, have not proliferated.

▲ **FIGURE 126-2** Localized infantile hemangioma, cheek of an infant.

▲ **FIGURE 126-3** Indeterminate infantile hemangioma, cheek, age 14 months.

▲ **FIGURE 126-4** Natural history of a deep infantile hemangioma, right cheek/parotid. **A.** Age 1 year, peak of proliferation. **B.** Age 3 years, involuting phase.

Medical and Extracutaneous Risks. Certain hemangiomas have known associated risks. Anatomic location is one of the most important clues to these risks. Sites such as the periocular, lumbosacral, or mandibular areas should lead to closer scrutiny. In addition, the presence of multiple or segmental hemangiomas is associated with greater risk of extracutaneous disease.[21]

PHACES. Facial segmental IH are associated with PHACES (Online Mendelian Inheritance in Man #606519), a neurocutaneous syndrome that consists of the following features: *p*osterior fossa brain malformations, segmental cervicofacial *h*emangioma, *a*rterial anomalies, cardiac defects or *c*oarctation of the aorta, *e*ye anomalies, and *s*ternal defects, such as sternal clefting or supraumbilical raphe.[27] Only one extracutaneous anomaly is required for diagnosis, thus the clinical spectrum varies considerably.[28] Posterior fossa malformations, particularly the Dandy-Walker malformation, are the most commonly reported feature of PHACE syndrome, and intracranial arterial defects can lead to a Moyamoya phenomenon, ischemia, and stroke.[29,30] Thus, brain imaging [magnetic resonance imaging (MRI) and magnetic resonance angiography] should be considered in all infants with a large segmental hemangioma of the face.[31] In addition, formal ophthalmologic examination and echocardiogram may be performed, given the relative frequency of anomalies in these sites.

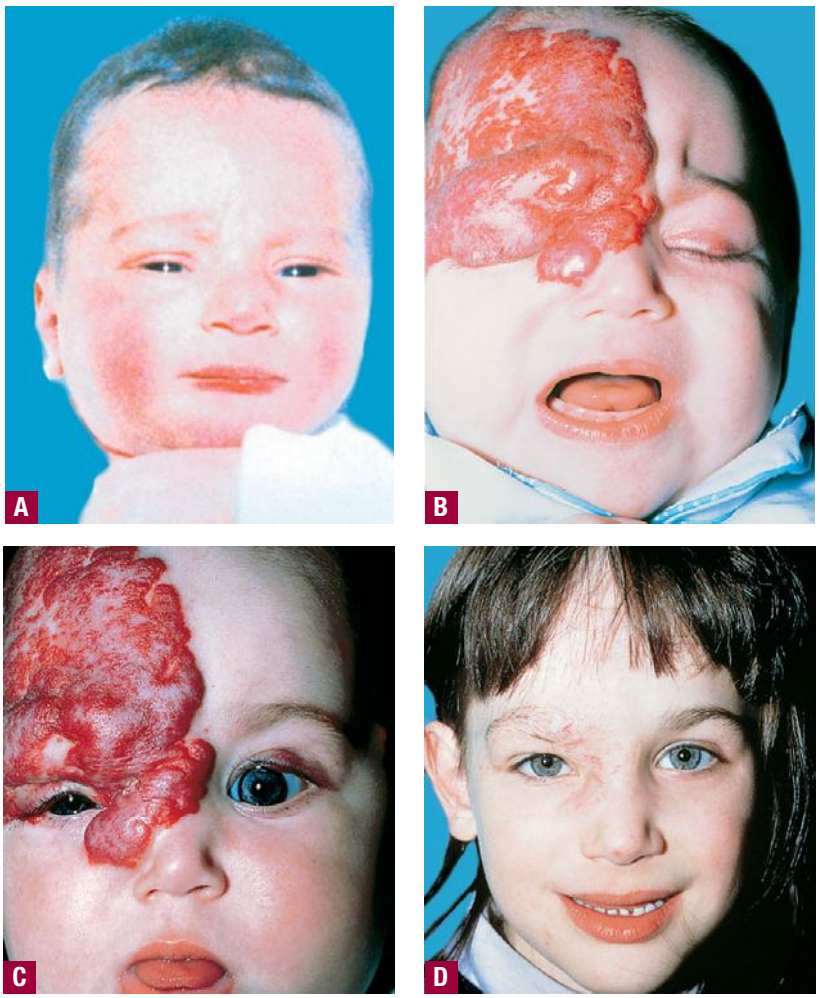
Periocular Hemangiomas. Infants with periocular hemangiomas are at risk for anisometropia and amblyopia, which if untreated, can lead to permanent visual loss (Fig. 126-6).[32] Direct pressure on the cornea can produce astigmatism or myopia, and the mass effect of the tumor itself can cause ptosis, proptosis, visual axis occlusion, or strabismus. Any patient with a hemangioma in the periocular area should have a prompt formal ophthalmologic evaluation with repeat visits during the proliferative phase (typically the first 3 to 4 months of life). Imaging studies may be needed to assess whether retrobulbar involvement is present.

"Beard Area" Hemangiomas. Segmental hemangiomas involving the preauricular, mandibular, chin, and neck skin (or so-called *beard area*) have a 60 percent risk of having symptomatic airway disease.[33] They usually present with the insidious onset of biphasic stridor between weeks 4 and 12 of life and are often mistakenly diagnosed as tracheomalacia, upper respiratory infection, or croup. If the hemangioma continues to enlarge, respiratory distress can ensue and become life-threatening. Prompt evaluation by a pediatric otolaryngologist and treatment is essential.[34] Hemangiomas can also involve the parotid gland, and often require treatment due to deformity of adjacent structures, and, in rare cases, high-output congestive heart failure.[35,36]

Lumbosacral and Perineal Hemangiomas. Segmental hemangiomas overlying the lumbosacral area can have associated spinal, bony, and genitourinary anomalies. Most frequently, posterior midline IH have a particularly high risk of spinal dysraphism and tethered cord, and MRI is strongly recommended.[37] Segmental perineal hemangiomas may be associated with urogenital and anorectal anomalies such as anterior or vestibular anus, hemiclitoris, atrophy or absence of the labia minora, and hypospadias.

Multifocal Hemangiomas. Multifocal IH are multiple, small (1 to 20 mm), noncontiguous lesions that can be confined to the skin but can also involve the viscera, termed *diffuse neonatal hemangiomatosis* (Fig. 126-7). Visceral hemangiomas are most commonly found in the liver (see hepatic IH) but have been reported in the lymph nodes, spleen, brain/meninges, iris, retina, salivary glands, thymus, gastrointestinal tract, lung, bladder, kidney, gallbladder, pancreas, and adrenal gland. Although most often described with multiple cutaneous hemangiomas, visceral hemangiomas have also been reported with solitary seg-

▲ **FIGURE 126-5** Telangiectatic infantile hemangioma, left foot. This lesion could be confused with a port-wine stain. **A.** Reticulated stain and minor soft-tissue hypertrophy. **B.** Age 11 years, only fine telangiectasias remain (involuted phase).



▲ **FIGURE 126-6** Vision-endangering segmental infantile hemangioma treated with systemic glucocorticoids. **A.** No premonitory signs of tumor seen on infant's photograph. **B.** By age 3 months, extensive infantile hemangioma infiltrating the upper lid and surrounding tissue, causing blocked vision. **C.** Eyelid opened within 2 weeks of glucocorticoid therapy. **D.** Involuted tumor, age 6 years.

mental hemangiomas.[38] The associated IH is most often located on the face but can be seen anywhere on the body. A combined prospective and retrospective study of 750 infants revealed 45 percent of infants with numerous small "miliary" hemangiomas have hepatic hemangiomas whereas 12 percent to 14 percent of those with three to five small lesions, six or more cutaneous hemangiomas, or one large (> 5 cm) lesion have involvement.[39]

▲ **FIGURE 126-7** Multifocal infantile hemangiomas in a 6-month-old infant. There are multiple, dome-shaped, erythematous papules on the left arm, flank, and back.

Hepatic Hemangiomas. The liver is the second most common site for IH and can be associated with hypothyroidism (see the section Laboratory Tests). Many hepatic hemangiomas are small, focal, low-flow lesions which are asymptomatic and unlikely to need treatment. However, those with high-flow or shunting (either arteriovenous or portovenous) are more likely to present with high-output cardiac failure, liver dysfunction, or abdominal compartment syndrome often requiring embolization or surgical intervention.[40,41] Infants with multiple hepatic tumors or left-to-right shunting typically present within the first 16 weeks of life with a clinical triad of hepatomegaly, congestive heart failure, and anemia. GLUT-1 immunohistochemical staining has revealed two distinct groups: GLUT-1–positive tumors, which are small, multifocal, histologically similar to IH, more common in females, and only symptomatic when numerous lesions were present; and GLUT-1–negative tumors, which have no gender predilection, are symptomatic at birth or shortly thereafter, and require aggressive medical and surgical intervention.[42] In most instances, ultrasound may be initially used as a screening technique followed by computed tomography or MRI if multiple, unusually large, or symptomatic hepatic hemangiomas are found.

LABORATORY TESTS ***Thyroid Function Tests.*** Hypothyroidism is a rare complication in infants with massive hemangiomas of the liver.[43,44] First reported by Huang et al., hemangioma tissue demonstrates high levels of type 3 iodothyronine deiodinase activity, which accelerates the degradation of thyroid hormone.[45,46] Infants with significant hepatic hemangiomas should have thyroid function evaluated, including T3 (the hormone consumed) and thyroid-stimulating hormone, because T4 levels may initially remain normal. Conversely, screening liver ultrasound looking for hemangiomas should be performed in infants with hypothyroidism of unknown etiology even in the absence of cutaneous hemangiomas.

Platelet Studies. Platelet studies are not indicated as the Kasabach-Merritt phenomenon (KMP) is not associated with IH but rather with kaposiform hemangioendothelioma (KHE) and tufted angioma (TA) (see the section Pharmacologic Therapy).

Recommended tests and imaging studies are included in the section Cutaneous Lesions with discussion of specific IH and their related physical findings.

Complications

Ulceration is the most common complication of IH, occurring in approximately 15 percent of patients usually during the proliferative phase. It occurs most frequently with segmental IH and at sites that are constantly exposed to moisture and friction such as the perioral, perianal, and other intertriginous sites.[47,48] Secondary infection can occur but its frequency is debatable. Cultures usually show polymicrobial growth and are

likely the result of colonization.[49] However, if infection is suspected, systemic antibiotics should be prescribed.

Local wound care, barrier protection, and pain control are essential for treatment. Bio-occlusive dressings may be helpful but those intended to stick to the skin may be limited by location because they do not adhere well near orifices.[50] In these areas, thick applications of petrolatum-based ointments can be helpful. Pain can be a major issue in management. It can be minimized with an occlusive dressing, oral acetaminophen with or without codeine, and the use of very small amounts of topical lidocaine ointment no more than a few times a day. Ulcerations generally heal with scarring within 2 to 3 weeks with topical care. For refractory cases, other treatment modalities including pulsed dye laser or Becaplermin 0.01% gel, a synthetic platelet-derived growth factor, have anecdotally been reported to be effective.[51,52] Therapies aimed at halting hemangioma growth, such as intralesional and systemic steroids or excision, may be useful in some cases.

Other serious complications such as hypothyroidism, internal organ involvement, or vital structure compromise due to the location of IH in certain anatomic sites have been discussed in the section Cutaneous Lesions.

Prognosis and Clinical Course

The prognosis of most IH is excellent, with spontaneous involution and little to no sequelae, but a significant minority can result in permanent disfigurement or medical sequelae. Certain characteristics are associated with an increased risk of complications and need for treatment (Table 126-2).[53] Consideration of early treatment should be given to hemangiomas with these characteristics, depending on the specific clinical setting.

Treatment

The decision to initiate treatment is based on many factors, including size and location, psychosocial implications, and risks and benefits of the proposed therapy. For the majority of small hemangiomas, "active nonintervention" is the most appropriate approach. This does not mean doing nothing. The infant should be seen frequently, especially during the first few months (corresponding to the proliferative phase). During these visits, education about the natural course of IH and discussions about the psychosocial impact on the child and/or the family should occur.[54] Photographs of the likely outcome for a similar lesion are often helpful. Many parents experience anxiety and may find themselves subject to comments from complete strangers about their child's hemangioma.[55] Most parents of young children do not think their child is deeply affected by these reactions, but facial hemangiomas in particular can cause psychological suffering once the child reaches school age.[56,57] Potential treatment options should be discussed well ahead of entrance to elementary school.

If it is decided that treatment is necessary, options include pharmacologic, laser, or surgical interventions. However, management remains controversial with few double-blind controlled studies and no Food and Drug Administration-approved labeled indications for medical treatments.

PHARMACOLOGIC THERAPY ***Corticosteroids.*** Systemic corticosteroids are the first-line treatment for deforming, endangering, or life-threatening IH (see Fig. 126-6).[58] They work best during the growth phase, causing slowing or cessation of growth in up to 90 percent of cases, with actual shrinkage in approximately one-third. Although the mechanism of action is not well understood, recent studies suggest the upregulation of mitochondrial cytochrome b, clusterin/ApoJ (possible apoptotic markers), and/or interleukin-6 as markers of corticosteroid-induced cessation of hemangioma growth.[59–61] Prednisone or prednisolone is given at a dose of 2 to 3 mg/kg/day, typically for 4 to 8 weeks followed by a tapering of varying length, depending on the age of the child and indication for treatment. A recent large meta-analysis showed an 84 percent response rate with an average dose of 2.9 mg/kg for a mean of 1.8 months before tapering. Although 3 mg/kg/day is more effective (94 percent response) than 2 mg/kg/day (75 percent response), greater adverse events are found with the higher dose.[62]

Short-term complications of systemic corticosteroids include: cushingoid facies (71 percent), personality changes (29 percent), gastric irritation (21 percent), fungal infection (oral or perineal, 6 percent), and diminished gain of height (35 percent) and weight (42 percent) during treatment. More than 90 percent of children with diminished gain of height return to their pre-treatment growth curve by 24 months of age (Table 126-3).[63] Other complications include hypertension, steroid-induced myopathy, and immunosuppression. Blood pressure should be monitored with each visit to the dermatologist or pediatrician.[64] Children taking more than 2 mg/kg/day of prednisone for longer than 14 days are considered to have a deficit in cell-mediated immunity. Live-viral vaccinations should be deferred in infants receiving high-dose corticosteroids. Rare cases of *Pneumocystis carinii* pneumonia have been reported in this setting, leading some physicians to use trimethoprim-sulfamethoxazole prophylaxis during treatment.[65]

Intralesional corticosteroids can be an effective treatment for relatively small localized hemangiomas located in high-risk sites such as the lip, nasal tip, cheek, and ear. Injections for periocular hemangiomas are usually performed by oph-

TABLE 126-2
High-Risk Infantile Hemangioma Sites and Sub-Types

Sub-types	Segmental, multifocal
Sites	Face—periorbital, perioral, any large facial; "beard" area; lumbosacral; genital

TABLE 126-3
Major Side Effects of Common Infantile Hemangioma Treatments

TREATMENT	MAJOR SIDE EFFECTS
Systemic corticosteroids	Diminished gain of height and weight, cushingoid facies, personality changes, gastric irritation, hypertension, immunosuppression
Intralesional corticosteroids	Arterial embolization/injection, atrophy, systemic absorption
Topical corticosteroids	Local atrophy, systemic absorption
Interferon-α	Spastic diplegia (neurotoxicity), fever, hepatotoxicity, neutropenia, anemia
Vincristine	Central line placement, neuropathy, abdominal pain, constipation
Laser	Pain, scarring, hypopigmentation, textural change, ulceration
Surgery	General anesthesia, scarring

thalmologists, but reports of retinal artery embolization and blindness have resulted in a reduced use of this modality.[66–68] The largest published case series of intralesional steroids found that the majority showed greater than 50 percent reduction in volume with the best results occurring in relatively superficial hemangiomas. Adverse events occurred in 6.4 percent of patients and included cushingoid appearance, cutaneous atrophy, and anaphylactic shock (see Table 126-3).[69]

A few case series have reported on the efficacy of class 1 topical corticosteroids, especially for small, superficial hemangiomas.[70–72]

Interferon-α. Interferon-α therapy is reserved for hemangiomas causing morbidity that are unresponsive to oral corticosteroids, or where such therapy is contraindicated. It is quite effective, but a severe neurotoxicity, spastic diplegia, has been reported in up to 20 percent of infants treated (see Table 126-3). A recent meta-analysis of 441 patients showed 11 developed irreversible spastic diplegia and 16 developed motor disturbances that were reversible on discontinuation of the drug.[73] All affected patients were younger than 1 year of age at initiation of therapy, suggesting that the drug may be safer after 1 year of age. Neurologic evaluations should also be performed monthly in treated children.

Chemotherapy. Vincristine is often used in the treatment of the KMP and its associated tumors, KHE and TA.[74–76] Given the potential neurotoxicity of interferon (see the section Interfon-α), vincristine is considered by some to be a second-line treatment for aggressive, complicated IH that do not respond to corticosteroids. However, further evaluation through prospective clinical trials is needed (see Table 126-3).

Cyclophosphamide has been reported in the pediatric hematology-oncology literature to be effective in the treatment of life-threatening diffuse neonatal hemangiomatosis.[77,78]

Imiquimod. Imiquimod 5% cream has anecdotally been reported to be effective in treating small superficial hemangiomas, but crusting and ulceration are potential side effects.[79–81]

LASER THERAPY The pulsed dye laser (PDL), originally designed to treat port-wine stains, has been used to treat IH with varying results.[82] Several reports have shown improvement in treating hemangioma ulceration,[83,84] and its use in diminishing residual telangiectasias and erythema after involution is well accepted. Its use in the treatment of proliferating hemangiomas is controversial.[85] Batta et al. performed the only prospective, randomized, controlled study to date regarding the treatment of IH in 121 patients aged 1 to 14 weeks, using 585-nm PDL without cooling compared to observation alone.[82] Their results showed no difference between complete and nearly complete clearance with laser compared to observation alone at age 1 year, with a trend toward increased hypopigmentation and textural change in the laser-treated group. Other studies have shown good results with either the 585-nm PDL or 595-nm PDL, with varying fluences, but several have emphasized that treatments work best for more superficial hemangiomas and are unable to halt growth of deeper components.[86–88] Severe ulceration and scarring, particularly in treating segmental hemangiomas during the proliferative phase, have been reported (see Table 126-3).[89] A conservative approach is to reserve PDL primarily for treating ulceration and for hastening resolution of erythema in IH that have stopped proliferating or have already undergone involution.[90]

SURGICAL THERAPY Surgical excision may be indicated at any time during the life cycle of an IH (Fig. 126-8).[1] In most instances, it is best to wait until regression is well under way and a more accurate assessment can be made regarding whether scarring and textural changes have occurred. Decisions regarding this can often be made at age 3 to 5 years, even if involution is not complete.[91] Certain anatomic locations such as the nasal tip and lip often require surgery.[92–97] Even earlier excision may be indicated in cases where clinical characteristics, such as pedunculated, very ulcerated, or extremely thick dermal involvement dictate that scarring will inevitably occur. A standard elliptical excision is often performed; however, circular excision followed by a purse-string closure may leave a smaller scar.[98]

▲ **FIGURE 126-8** Surgical correction of involuting-phase infantile hemangioma. **A.** Age 3 years, infantile hemangioma on upper eyelid. **B.** Age 9 years, after staged surgical resection, including vertical shortening of eyelid, repair of blepharoptosis, and formation of tarsal crease.

OTHER VASCULAR TUMORS

Many other benign vascular neoplasms occur in both children and adults.[99] This chapter highlights many of the important ones. More comprehensive reviews of this subject can be found elsewhere.[99–101]

Congenital Hemangiomas

Hemangiomas that are fully formed tumors at the time of birth and do not proliferate in postnatal life are referred to as *congenital hemangioma* or *congenital nonprogressive hemangioma*. There are two major sub-types recognized on the basis of their natural history: the rapidly involuting congenital hemangioma (RICH) and non-involuting congenital hemangioma (NICH).[102] Collectively, both are sometimes referred to as *congenital nonprogressive hemangioma*. The distinguishing pathologic features of these tumors are lobules of capillaries set within densely fibrotic stroma containing hemosiderin deposits, focal lobular thrombosis, and sclerosis.[103] They are GLUT-1 negative.[104] Both have similar anatomic sites of predilection, such as the extremities or postauricular skin, but they can occur elsewhere. RICH often appears as a raised, violaceous tu-

OTHER VASCULAR TUMORS AT A GLANCE

- Congenital hemangiomas are fully formed at birth. Rapidly involuting congenital hemangiomas and non-involuting congenital hemangiomas are recognized sub-types.
- Tufted angiomas represent subtle pink or dusky-red patches and may evolve into plaques or nodules and have a characteristic histology.
- Kaposiform hemangioma is morphologically similar to but etiologically distinct from Kaposi sarcoma and can be associated with Kasabach-Merritt phenomenon.
- Multifocal lymphangiomatosis with thrombocytopenia consists of cutaneous vascular papules and plaques associated with intermittent thrombocytopenia, often with gastrointestinal bleeding.
- Spindle cell hemangioendothelioma usually occurs in the extremities most often associated with Maffucci syndrome.
- Congenital eccrine angiomatous hamartoma is a rare ill-defined plaque associated with increased lanugo hair and sweating.
- Pyogenic granuloma is very common; a rapidly growing papule or nodule with a collarette of scale or eroded surface. Treatment is excision or electrocautery.

mor with large, radiating veins or with overlying telangiectasia and a halo of pallor (Fig. 126-9). Central ulceration may be present. Most RICH involute spontaneously by age 14 months, often sooner, and usually leave residual atrophic inelastic skin in their wake.[105]

NICH are also present at birth, but usually flatter than RICH, presenting as a well-circumscribed round to oval, slightly indurated or raised soft-tissue mass with overlying telangiectasias and a rim of pallor (Fig. 126-10).

Both NICH and RICH are high-flow vascular anomalies, often showing arteriovenous micro-fistulas on Doppler interrogation. Some cases of RICH involute only partially, and the residual tumor resembles NICH, supporting the concept that RICH and NICH may be variants of each other.

Indications for treatment of NICH or RICH are similar to those for IH, including impairment of visual function and congestive heart failure. Excision should definitely be considered for ulceration, which in this setting can lead to severe hemorrhage, and for post-involutional skin changes if disfiguring. NICH do not go away but are often asymptomatic; decisions regarding their removal must weigh risks and benefits of the proposed treatment.

▲ **FIGURE 126-10** Non-involuting congenital hemangioma on right mandible. Note the overlying telangiectasias and rim of pallor.

Tufted Angioma

ETIOLOGY TA is a benign vascular tumor that has also been called *angioblastoma of Nakagawa*. Its etiology and pathogenesis are uncertain. Unlike IH, there are no known gender or gestational age correlates.

CLINICAL FINDINGS Most cases are acquired early in childhood and have a protracted course. Rare congenital forms also exist. TAs display various clinical patterns. They may present as a subtle stain-like area that later thickens, as a large, plaque-like, infiltrated, red or dusky blue-purple lesion, or as an exophytic, firm, violaceous, cutaneous nodule (Fig. 126-11). TA must be differentiated from infantile hemangiomas as well as other vascular tumors. They are often somewhat firmer and may be tender. Histologically, both acquired and congenital TAs demonstrate vascular tufts of tightly packed capillaries, randomly dispersed throughout the dermis in a typical "cannonball distribution" with crescentic spaces surrounding the vascular tufts, and lymphatic-like spaces within the tumor stroma.[106,107]

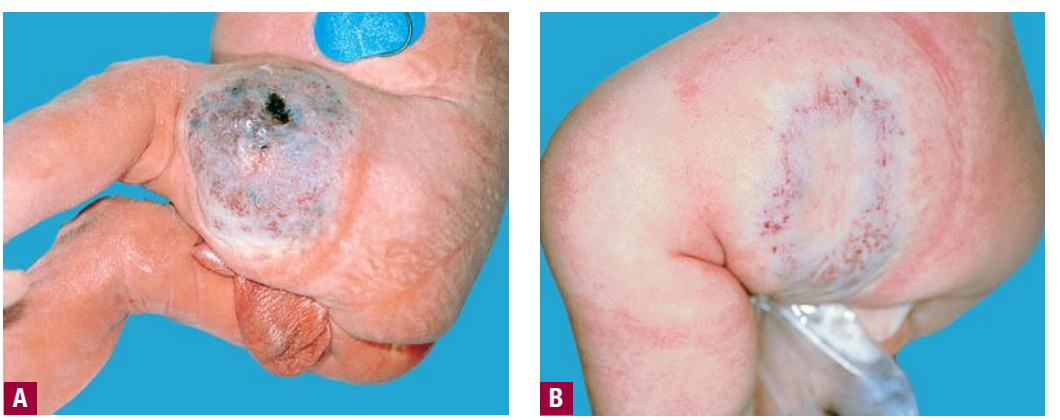
COMPLICATIONS KMP may develop in TA but this is more common with KHE (see the section Kaposiform Hemangioendothelioma).

PROGNOSIS AND CLINICAL COURSE TA may persist unchanged or regress completely within a few years.

TREATMENT No single treatment is effective. Interferon-α and PDL have anecdotally been reported to be effective.

Kaposiform Hemangioendothelioma

KHE is a rare vascular tumor that has usually been reported in association with



◀ **FIGURE 126-9** Rapidly involuting congenital hemangioma on left thigh. **A.** Note central ulceration, violaceous color, and pale periphery. Fast-flow vessels were detected on Doppler examination. **B.** Rapid regression at age 2 months.

▲ **FIGURE 126-11** Age 18 months. Tufted angioma (confirmed by biopsy) of the left leg, buttocks, lower abdomen. Laboratory evaluation revealed elevated D-dimers.

KMP. It may be present at birth or develop in early childhood. Rare adult cases have been reported. It may present as a brown-red stain at birth which begins to thicken and become purpuric, or as a plaque or nodule similar to tufted angioma. Regional lymph node involvement may occur, but not distant metastases. Spontaneous involution is rare. Most reported cases have had associated KMP, but the KHE can occur in the absence of a coagulopathy.[108,109]

The histology of KHE is characterized by spindled cells with minimal atypia and infrequent mitoses lining slit-like or crescentic vessels containing hemosiderin. The tumor is GLUT-1 negative. The overlap of both clinical and histologic features has led some to suggest that TA and KHE are part of a spectrum of disease. Increased lymphatic spaces have suggested a lymphatic origin, similar to that of Kaposi sarcoma.

Kasabach-Merritt Phenomenon

KMP has been used to describe infants with vascular tumors and thrombocytopenia with an associated coagulopathy (Fig. 126-12). It was long considered to be a complication of "hemangioma," but it is now recognized to be a complication of TA and KHE, not IH.[110,111]

KMP must be differentiated from a coagulopathy which can arise in association with venous and mixed venous-lymphatic malformations (sometimes erroneously called *KMP*) due to chronic clotting and consumption of clotting factors, but not primarily by platelet trapping.[112] The hallmark of KMP is severe thrombocytopenia. Consumption of fibrinogen, elevated D-dimers, and decreased coagulation factors occurs to

▲ **FIGURE 126-12** Kasabach-Merritt phenomenon secondary to kaposiform hemangioendothelioma. An indurated, purpuric tumor appeared at age 3 months and is seen here at age 8 months. Kaposiform hemangioendothelioma confirmed by magnetic resonance imaging and biopsy. Platelet count < 5000/mm^3.

varying degrees. Most cases involve the skin and musculature, but deeper viscera including cervicothoracic, abdominal, and pelvic regions can be affected. Although the tumors causing KMP can persist, the coagulopathy usually abates by 1 year of age or sooner with treatment. KMP may resolve with atrophic or stain-like areas, infiltrated plaques and papules, or nodules. Residual fibrosis is not rare and can result in considerable morbidity.[113]

No one treatment is uniformly effective. Options include corticosteroids, vincristine, cyclophosphamide, actinomycin-D, methotrexate, interferon-α, ticlopidine plus aspirin, surgical excision, arterial embolization, and radiotherapy. Platelet transfusions should be avoided unless active bleeding occurs or before surgical procedures.[114,115]

Multifocal Lymphangioendotheliomatosis with Thrombocytopenia

Multifocal lymphangioendotheliomatosis with thrombocytopenia (also known as *cutaneovisceral angiomatosis with thrombocytopenia*), a rare condition, is characterized by multiple cutaneous vascular papules and plaques that are usually present at birth with more developing over time. Affected infants have intermittent thrombocytopenia and lesions in the gastrointestinal tract, leading to gastrointestinal bleeding. Other reported sites of involvement include bones, synovium, lungs, liver, and spleen. Skin biopsy specimens demonstrate thin-walled vessels, some hobnailed endothelial cells, and intraluminal papillary projections similar to Dabska tumor.[116,117]

Spindle Cell Hemangioendothelioma

Spindle cell hemangioendothelioma is a rare vascular tumor most often seen with Maffucci syndrome. It can occur at any age and site but the extremities are the most commonly affected. The histology is of a nodular, dense, spindle cell proliferation in association with dilated dysplastic veins. Lesions can be locally aggressive and may recur even after excision.[118]

Congenital Eccrine Angiomatous Hamartoma (Sudoriparous Angioma)

Congenital eccrine angiomatous hamartoma is a rare condition characterized by ill-defined plaques with increased lanugo hair and sweating at the site of the lesion. They are usually located on the extremities or abdomen. Diagnosis is established on the basis of characteristic histologic findings: closely packed eccrine sweat glands associated with dilated capillaries, a few dysplastic venous channels, and a dense collagenous matrix.[119]

Pyogenic Granuloma (Lobular Capillary Hemangioma)

Pyogenic granuloma (PG) is also known by its correct histopathologic description *lobular capillary hemangioma.* It is one of the most common vascular tumors of infants and children and can also occur in adults, particularly in pregnant women. PG usually presents as a solitary, red, rapidly growing papule or nodule, often with a subtle collarette of scale (Fig. 126-13). Typical locations include the cheek or forehead but virtually any body site may be affected. They often develop an

▲ **FIGURE 126-13** Large pyogenic granuloma on chest, age 2 years.

eroded surface, with subsequent bleeding which can be profuse, resulting in the moniker *the band-aid disease*. In very young infants, PG is often mistaken for an infantile hemangioma.[120]

PG does not involute spontaneously, but simple curettage with electrocautery is usually curative. Other options include excision, laser surgery (carbon dioxide or pulsed dye), and cryotherapy. Recurrence and even satellite lesions surrounding the original PG have been reported.[121,122]

Other Vascular Tumors

Targetoid hemosiderotic hemangioma is a benign lesion presenting as a violaceous papule, often surrounded by a pale rim and peripheral ecchymotic halo, which fades with time. Lesions usually present on the trunk or extremities and histologically consist of dilated vascular channels within intraluminal papillary projections dissecting into collagen bundles in the subcutis. Extravasated erythrocytes and hemosiderin are present, hence the designation.

Endovascular papillary angioendothelioma (Dabska tumor) is a dermal nodule or a diffuse swelling on the head, neck, or extremities. Dabska tumor is a low-grade angiosarcoma. Epithelioid hemangioendothelioma and retiform hemangioendothelioma are other examples of low-grade angiosarcomas. These tumors, Kaposi sarcoma, and angiosarcoma are discussed in Chap. 128. Vascular malformations are discussed in Chap. 173.

CHAPTER 127

Neoplasias and Hyperplasias of Muscular and Neural Origin

Lucile E. White
Ross M. Levy
Murad Alam

TUMORS OF SMOOTH MUSCLE

The dermis contains smooth muscle fibers in the arrector pili muscles, in the walls of dermal blood vessels, and in the dartos muscle of the scrotum, vulva, nipple, and areola. There are three types of cutaneous smooth muscle lesions: leiomyomas, leiomyosarcomas, and hamartomas. Smooth muscle is recognized histologically by spindle cell shape, eosinophilic, fibrillary cytoplasm, and blunt-ended, oval, "cigar-shaped" nuclei. On immunohistochemical staining, cells express smooth muscle actin and the muscle-specific intermediate filament desmin, but are negative for S100 protein and epithelial membrane antigen (EMA).

Leiomyoma

EPIDEMIOLOGY The exact incidence of leiomyomas is unknown. In one study, the 10-year incidence was 0.04 percent with the majority of lesions occurring in women.[1] Although leiomyomas are thought to be relatively uncommon neoplasms, the actual incidence may be higher than previously believed due to failure to recognize and biopsy the lesion.

ETIOLOGY AND PATHOGENESIS Cutaneous leiomyomas are divided into three subsets: (1) solitary or multiple piloleiomyomas originating from the arrector pili muscles; (2) genital leiomyomas originating from the mammillary, dartoic, or labial/vulvar muscles; and (3) angioleiomyomas, originating from vascular smooth muscle. Most leiomyomas are acquired; however, familial inheritance patterns have been described. Especially noteworthy are patients with multiple piloleiomyomas. Starting in early adulthood, these patients present with increasing numbers of tumors, developing as many as 100 to 1000 lesions. Transmission appears to be autosomal dominant with variable penetrance.[2] Women with multiple piloleiomyomas may also develop uterine leiomyomas, an entity termed *multiple cutaneous and uterine leiomyomatosis* (also known as *familial leiomyomatosis cutis et uteri* or *Reed syndrome*).[2] In addition, some families with multiple cutaneous and uterine leiomyomatosis have been shown to cluster renal cell cancer, and this has been termed *hereditary leiomyomatosis and renal cell cancer*. Recently, a loss of function mutation in the gene encoding fumarate hydratase on chromosome 1q42.3-43 has been shown to predispose individuals to these conditions. Fumarate hydratase catalyses the conversion of fumarate to malate in the Krebs cycle but is also considered to be to be a tumor suppressor gene.[3]

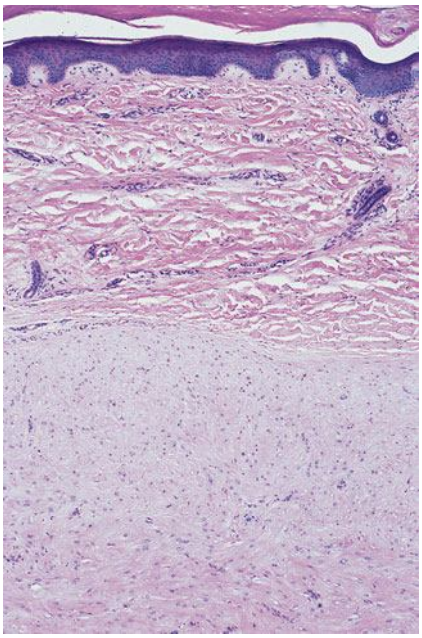
LEIOMYOMA AT A GLANCE

- Benign cutaneous neoplasm derived from arrector pili muscle (piloleiomyoma), mammillary, dartoic or labial/vulvar muscle (genital leiomyoma), or the walls of blood vessels (angioleiomyoma).
- Present as solitary or multiple flesh-colored, occasionally painful papules; rarely associated with uterine leiomyomas and renal cell cancer.
- Treatment: Surgical; recurrence is common.

▲ **FIGURE 127-1** Clinical photograph showing multiple leiomyomas involving the back.

CLINICAL FINDINGS The most common presentation is that of multiple pilole iomyomas.[4] Individual lesions range in size from several millimeters to 1 cm and are usually reddish-brown firm papulonodules that are fixed to the skin but freely moveable over underling deeper structures (Fig. 127-1). They can coalesce to form plaques or linear, grouped, or dermatomal patterns.[4] The extensor extremities, trunk, and sides of the face and neck are the most common locations. Patients with piloleiomyomas often have pain that may be spontaneous or secondary to cold, pressure, or emotion.[2,4–6] Possible explanations for this phenomenon include pressure of the tumor on local nerve fibers and contraction of the smooth muscle fibers.[4] Genital leiomyomas are clinically similar to piloleiomyomas except that they are usually asymptomatic.[4] They commonly present as solitary, deep papulonodules or occasionally, pedunculated papules on the scrotum, vulva, penis, or areolar region. Angioleiomyomas present most commonly as solitary, painful subcutaneous nodules on the legs in women that can grow to several centimeters in diameter.[7]

HISTOPATHOLOGY Pilar leiomyomas are composed of a poorly circumscribed proliferation of haphazardly arranged, bland-appearing smooth muscle cells with characteristic eosinophilic cytoplasm, blunt-ended nuclei and perinuclear halos in cross-section. They are located in the dermis and can infiltrate the surrounding tissue with extension into the subcutis (see eFig. 127-1.1 in on-line edition). Genital leiomyomas usually resemble pilar leiomyomas. Angioleiomyomas are well-circumscribed, richly vascularized dermal or subcutaneous nodules composed of well-differentiated smooth muscle fibers (Fig. 127-2).



▲ **FIGURE 127-2** Histologic appearance of an angioleiomyoma. Compared with the pilar leiomyoma, this tumor is more sharply circumscribed (but not encapsulated). Furthermore, the smooth muscle fibers form a solid nodule with little, if any, intervening collagen. (Hematoxylin and eosin, ×40.)

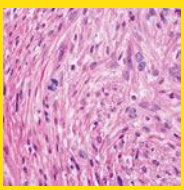
Occasionally, the vessel of origin can be identified. Leiomyomas stain positive with smooth-muscle actin and desmin.

DIFFERENTIAL DIAGNOSIS Differential diagnosis of leiomyoma includes any flesh-colored or reddish-brown superficial or deep-seated papule or nodule: angiolipoma, glomus tumor, eccrine spiradenoma, neurofibroma, nevus, or lipoma.

PROGNOSIS AND CLINICAL COURSE Cutaneous leiomyomas do not regress spontaneously, and there does not appear to be risk of malignant degeneration into leiomyosarcoma. A minority of patients may also develop uterine leiomyomas and, in some families, association with renal cell carcinoma has been described. Occasionally, leiomyomas are associated with polycythemia. This may be due to erythropoietin-like activity of leiomyomas, which has been demonstrated in tumor extracts.[8]

TREATMENT Excision is the treatment of choice for leiomyomas that cause pain or cosmetic concern; however, recurrence is common. In patients with numerous lesions, this method is impractical. Carbon dioxide laser ablation was reported as an effective modality[9] whereas cryotherapy and electrosurgery have been used with disappointing results.[10] Pain may be a significant source of morbidity and, when surgical intervention is not possible, potential treatment options include nitroglycerin, phenoxybenzamine, nifedipine, gabapentin, or topical analgesics.[2,11–13]

LEIOMYOSARCOMA AT A GLANCE



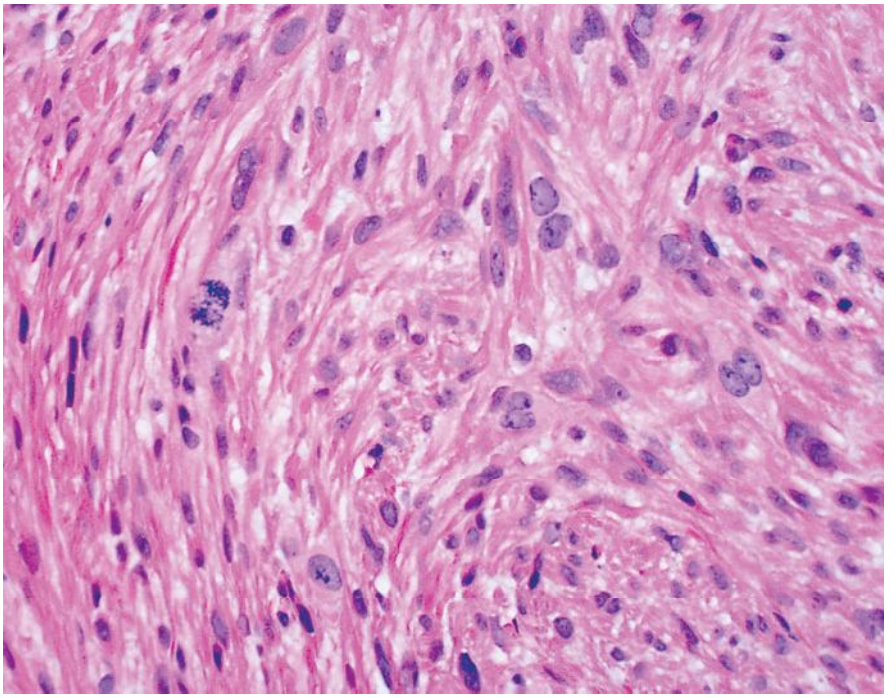
- Rare malignant tumor of smooth muscle: Cutaneous and subcutaneous types based on location of origin.
- Presentation: Enlarging cutaneous or subcutaneous tumor most commonly on hair-bearing areas of the lower extremities.
- Recurrence rate: High, with significant risk of metastases in case of subcutaneous leiomyosarcoma.

Leiomyosarcoma

EPIDEMIOLOGY Exact incidence is unknown, but older studies suggest that leiomyosarcomas comprise approximately 3 percent of soft-tissue sarcomas.[14] Superficial leiomyosarcoma occurs in all age groups, and there appears to be no gender predilection.

ETIOLOGY AND PATHOGENESIS Leiomyosarcoma is a rare, malignant mesenchymal tumor of smooth muscle origin usually found in the uterus, the retroperitoneum, gastrointestinal tract, or deep soft tissue. The term *superficial leiomyosarcomas* refers to those tumors whose primary site of origin is the skin. Those derived from arrector pili or genital smooth muscles are termed *cutaneous leiomyosarcomas*, and those derived from blood vessel smooth muscle are termed *subcutaneous leiomyosarcomas*. In some cases, tumors have arisen in sites of earlier radiotherapy or trauma.[4] Leiomyosarcomas typically arise de novo rather than from pre-existing leiomyomas.

CLINICAL FINDINGS Leiomyosarcomas present as solitary, enlarging lesions most commonly on the hair-bearing ar-



▲ **FIGURE 127-3** Histologic examination of a leiomyosarcoma. This tumor exhibits smooth muscle differentiation with atypical cytologic features such as nuclear hyperchromasia, prominent nucleoli, and mitoses. (Hematoxylin and eosin, ×400.)

eas of lower extremities.[19] They can exhibit a variety of colors and may be painful, pruritic, or paresthetic. Cutaneous leiomyosarcoma usually presents as small (< 2 cm), sometimes ulcerated nodules that are fixed to the epidermis. Subcutaneous leiomyosarcomas tend to be larger and are usually not associated with epidermal change. Some patients have multiple grouped lesions; in one series, four of seven such patients had a previous retroperitoneal leiomyosarcoma,[15] highlighting the importance of ruling out metastases in patients with numerous superficial leiomyosarcomas.

HISTOPATHOLOGY Leiomyosarcomas are large tumors consisting of smooth muscle fibers arranged in irregular, intersecting bundles and fascicles in the dermis and subcutis, often with infiltrating borders. Tumor cells exhibit smooth muscle differentiation with atypical cytologic features such as nuclear hyperchromasia, prominent nucleoli, mitosis, and necrosis (Fig. 127-3). In less well-differentiated areas, highly pleomorphic and multinucleated cells may be found.[4] Granular cell, epithelioid cell, myxoid, and sclerosing (or desmoplastic) variants have been described.[16] Leiomyosarcomas must be histopathologically distinguished from other malignant cutaneous spindle cell tumors, such as spindle cell melanoma, spindle cell squamous cell carcinoma, or atypical fibroxanthoma. Leiomyosarcomas stain positive with smooth-muscle actin, desmin, and vimentin and occasionally with S100 and cytokeratin, which makes distinguishing them from melanoma and squamous cell carcinoma difficult in certain cases.[4,17,18]

DIFFERENTIAL DIAGNOSIS Differential diagnosis of leiomyosarcoma includes any solitary, enlarging dermal or subcutaneous nodule: lipoma, dermatofibroma, dermatofibrosarcoma, neurofibroma, spindle cell melanoma, spindle cell squamous cell carcinoma, and atypical fibroxanthoma.

PROGNOSIS AND CLINICAL COURSE The most important prognostic factor depends on whether the leiomyosarcoma is of cutaneous or subcutaneous origin. Although both cutaneous and subcutaneous lesions may recur locally in up to one-third to one-half of cases, the risk of metastasis is 5 percent to 10 percent for cutaneous leiomyosarcomas compared with 30 percent to 60 percent for subcutaneous leiomyosarcomas.[4,8,14,19–23] The lung is the most common location of metastasis.

TREATMENT Therapy for superficial leiomyosarcoma is wide local excision with 3- to 5-cm margins and re-excision for recurrent lesions.[19] On acral locations, complete excision may require amputation.[19] Patients with subcutaneous leiomyosarcomas should undergo a chest x-ray for metastases. Adjuvant radiation and/or chemotherapy has unclear benefit. Alternative local treatment modalities in selected patients include Mohs micrographic surgery, cryosurgery, and isolated limb perfusion with chemotherapeutic agents.[19,24]

SMOOTH MUSCLE HAMARTOMA

AT A GLANCE

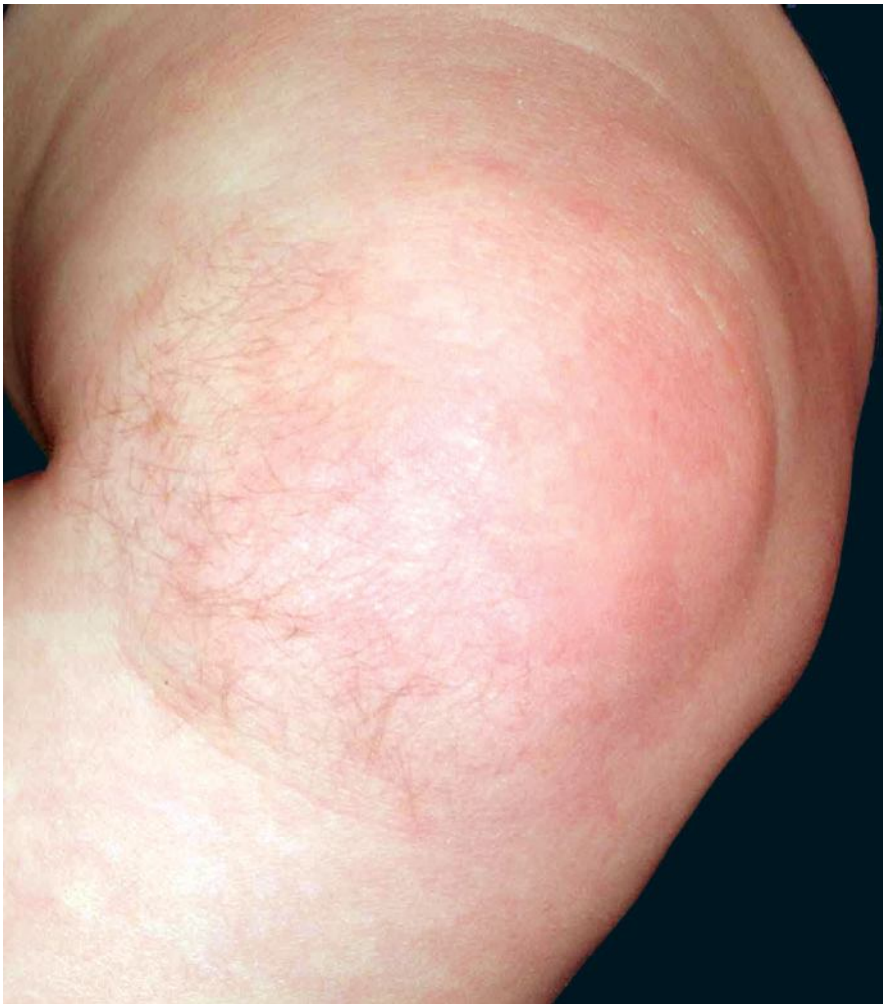
- Benign hamartomatous proliferation of smooth muscle.
- Presenting as a solitary patch or plaque on the trunk.
- Associated with variable pigmentation, hypertrichosis, and follicular prominence.
- Clinical and histologic features similar to Becker's nevus.

Smooth Muscle Hamartoma

EPIDEMIOLOGY First described by Stokes in 1923,[25] smooth muscle hamartoma has become increasingly recognized during the last two decades. Most cases are congenital but some are acquired,[26,27] and prevalence estimates of up to 0.2 percent in children have been reported.[27]

ETIOLOGY AND PATHOGENESIS Smooth muscle hamartoma is a benign proliferation of mature smooth muscle. The cause is unknown, and the majority of cases are present from birth.

CLINICAL FINDINGS Smooth muscle hamartoma is usually found on the trunk or extremity (Fig. 127-4) and may take one of several forms: a single patch or plaque with or without follicular prominence, grouped solitary lesions (rarely with a linear distribution), and diffuse skin involvement as seen in the Michelin tire baby syndrome.[28,29] Lesions can exhibit variable hyperpigmentation and hypertrichosis. Vellus hairs may be prominent. Some can produce worm-like movements ("vermiculation"), and stroking may induce transient induration with piloerection ("pseudo-Darier sign"). Smooth muscle hamartoma shares some clinical and histologic features with Becker's nevus. Some authors consider these lesions a



▲ **FIGURE 127-4** Smooth muscle hamartoma. This tumor presented with a focal area of hypertrichosis on the leg. (Photo from the collection of Dr. Amy Paller, MD, Children's Memorial Hospital, Chicago, IL.)

spectrum,[27] whereas others prefer to keep them separate.[26,30]

HISTOPATHOLOGY There is a marked increase of sharply circumscribed bundles of smooth muscle fibers that are haphazardly arranged in the reticular dermis. These fibers are sometimes associated with follicular units. There may be basal layer hyperpigmentation, as well as acanthosis and papillomatosis of the overlying epidermis. Factors that help to distinguish smooth muscle hamartomas from pilar leiomyomas include the grouping of smooth muscle fibers into discrete bundles and the lack of intermingling of these bundles with dermal collagen fibers.

DIFFERENTIAL DIAGNOSIS Differential diagnosis of hamartoma includes congenital nevus, Becker's nevus, café-au-lait macule, leiomyoma, neurofibroma, and solitary mastocytoma.

PROGNOSIS AND CLINICAL COURSE Malignant degeneration has not been reported. Although the localized form is usually not associated with other congenital anomalies,[27] patients with the generalized form have been reported to have multiple associated congenital malformations[31] and psychomotor retardation.[31,32]

TREATMENT No specific treatment is indicated. Surgical excision can be performed if the lesions are of cosmetic concern.

TUMORS OF STRIATED MUSCLE

Tumors of striated muscle include true neoplasms of striated muscle differentiation (rhabdomyomas and rhabdomyosarcomas) as well as non-neoplastic neuromuscular and rhabdomyomatous mesenchymal hamartomas (RMHs).

Rhabdomyoma

EPIDEMIOLOGY Extracardiac rhabdomyomas are extremely rare and comprise fewer than 2 percent of striated muscle neoplasms.[33] The adult and fetal types of rhabdomyomas occur predominantly in male patients. Cardiac rhabdomyomas occur in approximately 30 percent to 50 percent of patients with tuberous sclerosis (TS; see Chap. 141).[34]

ETIOLOGY AND PATHOGENESIS Rhabdomyomas are benign tumors of striated muscle. Extracardiac rhabdomyomas are not associated with TS, whereas a significant portion of patients with cardiac rhabdomyomas are ultimately diagnosed with TS.

CLINICAL FINDINGS Extracardiac rhabdomyomas are subdivided into three types: adult, fetal, and genital.[33,35] The designation as *adult* or *fetal* refers to the tumor's resemblance to adult or fetal skeletal muscle, not to the age of the patient.[35] Adult and fetal types usually arise in the soft tissues or mucosal surfaces of the head and neck region soon after birth. They are usually asymptomatic. The fetal type has been repeatedly associated with basal cell nevus syndrome.[35] Genital rhabdomyomas usually occur as small polypoid vaginal or vulvar lesions in middle-aged women.[35]

HISTOPATHOLOGY Rhabdomyomas are composed of fascicles of oval and polygonal-shaped cells with eosinophilic, often vacuolar cytoplasm and eccentrically placed nuclei.[33] Atypia, mitosis, and pleomorphism are absent.

DIFFERENTIAL DIAGNOSIS Differential diagnosis of rhabdomyomas includes granular cell tumor (GCT), hibernoma, and reticulohistiocytoma.

PROGNOSIS AND CLINICAL COURSE Extracardiac and cardiac rhabdomyomas have a very low risk of malignant degeneration. Many cardiac rhabdomyomas regress spontaneously with age.

TREATMENT The treatment of choice for symptomatic extracardiac rhabdomyomas is surgical excision.

RHABDOMYOMA AT A GLANCE

- Benign neoplasms of striated muscle.
- Most common on the head and neck of young males.
- Non-cardiac rhabdomyomas usually asymptomatic.
- Surgical excision is treatment of choice.

RHABDOMYOSARCOMA AT A GLANCE

- Malignant neoplasm of striated muscle.
- Most common soft-tissue sarcoma in children.
- Presentation: Subcutaneous or ulcerated tumor on extremities or head and neck; rare cause of "blueberry muffin baby."
- Treatment: Surgical excision, chemotherapy, and/or radiotherapy.
- Prognosis: Poor.

Rhabdomyosarcoma

EPIDEMIOLOGY Rhabdomyosarcoma is the most frequent soft-tissue sarcoma of childhood with annual incidence of 4.3/million, accounting for approximately 50 percent of soft-tissue sarcomas in children younger than age 15 years and 5 percent to 8 percent of all childhood cancers.[36–38] Only approximately 0.7 percent occur as primary skin lesions.[38] Males are more commonly affected than females.[36]

ETIOLOGY AND PATHOGENESIS Rhabdomyosarcomas are malignant neoplasms derived from skeletal muscle precursors. Primary cutaneous disease is rare, and skin involvement is more commonly a result of either direct extension from underlying soft tissues or metastases.[39] Four sub-types have been described based on histologic appearance: embryonal, alveolar, botryoid, and pleomorphic. The embryonal type is most common, followed by alveolar. Alveolar rhabdomyosarcoma is characterized at the molecular level by novel fusion genes combining the forkhead (*FKHR*) gene with either the *PAX3* or the *PAX7* gene, producing a t(2;13)(q35;q14) or t(1;13)(p36;q14), respectively.[36]

CLINICAL FINDINGS Cutaneous rhabdomyosarcoma typically presents as an enlarging subcutaneous or ulcerated tumor involving the head and neck, the genitourinary tract, or the extremities. A deep soft-tissue rhabdomyosarcoma can also extend into the overlying skin and present as a cutaneous nodule.[38] In neonates, congenital alveolar rhabdomyosarcoma is a very rare cause of "blueberry muffin baby" in which multiple cutaneous and subcutaneous metastases present as scattered blue nodules.

HISTOPATHOLOGY Rhabdomyosarcoma is composed of sheets of pleomorphic, small blue cells infiltrating the dermis and subcutaneous tissue. High mitotic index is present, and focal areas of necrosis can often be identified.[39] The embryonic type is composed of interlocking bands of spindle cells and sheets of small round cells whereas the alveolar type exhibits loss of cellular cohesion leading to spaces resembling alveoli. Immunohistochemistry can be helpful in differentiating rhabdomyosarcoma from other "small blue cell tumors." Rhabdomyosarcomas express positivity for muscle-specific actin, desmin, myoD1, and myogenin. Reverse transcription polymerase chain reaction and fluorescence in situ hybridization analysis can used to detect the t(2;13)(q35;q14) and t(1;13)(p36;q14) chromosomal translocations.[36,39]

DIFFERENTIAL DIAGNOSIS Differential diagnosis of rhabdomyosarcoma includes hemangioma, hematoma, neuroblastoma, and other soft-tissue sarcomas.

PROGNOSIS AND CLINICAL COURSE Prognosis is poor, with many patients succumbing to their disease. Even with appropriate treatment, rhabdomyosarcomas can recur and metastasize to regional lymph nodes, lung, bone, and heart. Congenital alveolar rhabdomyosarcoma has an especially poor prognosis: There are no reports in the literature of survivors.[36]

TREATMENT Treatment of rhabdomyosarcoma consists of a combination of surgical excision, chemotherapy, and radiotherapy.

Neuromuscular Hamartoma

Rhabdomyomatous Mesenchymal Hamartoma

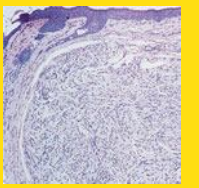
BENIGN PROLIFERATIONS OF NERVES: NEUROMAS

Traumatic (Amputation) Neuroma

EPIDEMIOLOGY The exact incidence of traumatic neuromas is not known. Several small studies suggest that up to 30 percent of amputations result in neuromas.[42,43]

ETIOLOGY AND PATHOGENESIS When a nerve is partially or completely severed, axons and Schwann cells can proliferate from the proximal stump and form a disorganized tangle of nerves and fibroblasts, called a *traumatic neuroma*. Within the bundle of nerves and fibroblasts, the axons can begin to synapse and send pain signals. These signals occur spontaneously or after mechanical thresholds lower than in normal nerves. The nerve proliferation typical of accessory digits may also represent an example of traumatic neuroma.

NEUROMAS AT A GLANCE



- Nonneoplastic overgrowths of nerves; benign
- Consist of both Schwann cells and axons
- Presentation: Flesh-colored papules or nodules
- Treatment: Excision

CLINICAL FINDINGS Traumatic neuromas are flesh-colored papules or nodules occurring at the sites of previous trauma or surgery. They often occur within suture lines and can be very painful.

HISTOPATHOLOGY Histologically, a neuroma appears as a collection of nerve fascicles that are haphazardly arranged. A fibrous or collagen sheath may surround neuromas, but these neuromas are not encapsulated by perineurium. The neuromas stain for EMA. Staining of the neural lesions is reviewed in Table 127-1.

DIFFERENTIAL DIAGNOSIS Differential diagnosis of neuromas includes hypertrophic scar, dermatofibroma, digital fibrokeratoma, and verruca vulgaris.

TREATMENT Temporary pain relief can be achieved with a local anesthetic nerve block. For more permanent pain relief, surgical treatment aims either at isolating the nerve from injury or excising the neuroma.[44]

TABLE 127-1
Staining of Neural Hyperplasias and Neoplasms

Neural Proliferation	S100	Neurofilament	Epithelial Membrane Antigen (EMA)	Other
Traumatic neuroma	+	+	+	Neuron-specific enolase positive
Palisaded encapsulated neuroma	+	+	+ for the capsule	
Schwannoma	+	–	+ for the capsule only	Vimentin positive
Neurofibroma	+	Variable	–	
Plexiform neurofibroma	+	+		
Neurothekeoma	+	–	Variable	Vimentin variable; usually EMA negative
Cellular neurothekeoma	–		–	CD57 positive; Ki-Mip positive
Perineurioma	–	–	+	Vimentin positive; neuron-specific enolase negative
Malignant peripheral nerve sheath tumor	+	+	Variable	Vimentin variable; cytokeratin negative; neuron-specific enolase positive
Primitive neuroectodermal tumor	+ if differentiated			Neuron-specific enolase positive; CD99 positive
Granular cell tumor	+			Neuron-specific enolase positive

+ = positive; – = negative.

Palisaded Encapsulated Neuroma

EPIDEMIOLOGY Palisaded encapsulated neuromas (PENs) present in adults, mostly in their third to fifth decade. There appears to be no gender predilection. PENs makes up approximately one-fourth of benign cutaneous neural lesions.[45]

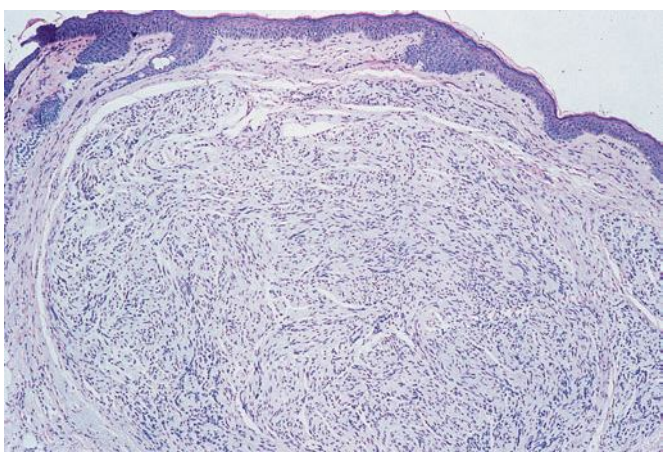
ETIOLOGY AND PATHOGENESIS PENs consist of a hamartomatous overgrowth of Schwann cells.[46] The etiology is unknown.

CLINICAL FINDINGS PENs often present as asymptomatic, flesh-colored papules or nodules that are smaller than 1 cm in diameter. PENs are located on the face in approximately 80 percent of cases.[45] PEN is almost never diagnosed clinically; the most common misdiagnoses are dermal melanocytic nevus, basal cell carcinoma, and adnexal tumor.

HISTOPATHOLOGY PENs are well-demarcated dermal nodules composed of fascicles of Schwann cells (Fig. 127-5). Contrary to what the name implies, the capsule is rarely complete and the palisading typical of schwannomas is often indistinct. Special stains demonstrate variable numbers of axons within the lesion. The capsule often stains with EMA, suggesting a perineural origin, and the tumor body stains for S100, suggesting a Schwann cell origin (see Table 127-1).[47,48] Some PENs may actually be small dermal schwannomas that contain a few residual entrapped axons.[49]

DIFFERENTIAL DIAGNOSIS Differential diagnosis of PEN includes dermal melanocytic nevus, basal cell carcinoma, adnexal tumor, and neurofibroma.

TREATMENT Excision is the treatment of choice. There is no evidence of an association between PEN and neurofibromatosis (NF; see Chap. 142) or multiple endocrine neoplasia syndrome type 2B (MEN2B; see Mucosal Neuromas and Multiple Endocrine Neoplasia Syndrome Type 2B).



▲ **FIGURE 127-5** Histologic appearance of a typical palisaded encapsulated neuroma. The tumor is composed of fascicles of Schwann cells and surrounded by a delicate capsule best seen on the left. There is a suggestion of nuclear palisading, but this is not as pronounced as that seen in a schwannoma. (The axons that are normally also present cannot be seen on this stain; hematoxylin and eosin, ×40.)

Mucosal Neuromas and Multiple Endocrine Neoplasia Syndrome Type 2B

EPIDEMIOLOGY Due to inconsistent nomenclature, the incidence of mucosal neuromas is not known.[50]

ETIOLOGY AND PATHOGENESIS MEN2B is an autosomal dominant condition. MEN2B is caused by germline mutations of the *RET* proto-oncogene located on chromosome 10q11.2.[51] The mutation is a result of substituting a threonine for a methionine in the tyrosine kinase domain of the RET protein.[49]

CLINICAL FINDINGS MEN2A is characterized by the triad of medullary carcinoma of the thyroid gland, pheochromocytoma, and parathyroid hyperplasia. The neoplastic spectrum of MEN2B is similar, but in addition, these patients have malformations (marfanoid habitus, facial dysmorphism) and overgrowth of mucosal nerves leading to the mucosal neuromas.[53]

The neuromas appear by 2 years of age and thus serve as an important clinical marker for identifying affected individuals in MEN2B families.[51] The neuromas involve all mucosal surfaces (oral mucosa, lips, tongue, conjunctivae) and appear as pink, pedunculated papules or nodules. The lips become enlarged and bulging, and the eyelids may be everted. Other cutaneous lesions include café-au-lait spots, facial lentigines, and hyperpigmentation of the hands and feet.

HISTOPATHOLOGY Histologically, there is hypertrophy of the mucosal nerves; some lesions may resemble PENs.

DIFFERENTIAL DIAGNOSIS Differential diagnosis of mucosal neuromas and MEN2B includes PEN and mucocele.

TREATMENT The main threat to these patients is the development of related cancers. Virtually all patients have a medullary carcinoma of the thyroid by early adulthood, and approximately one-half develop pheochromocytomas. The thyroid carcinoma is highly aggressive. Early detection and prophylactic thyroidectomy by 5 years of age are essential.[51]

OTHER NEUROMAS

Morton Neuroma

Hyperplastic/Hypertrophic Pacinian Corpuscle

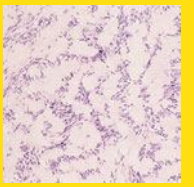
BENIGN NERVE SHEATH NEOPLASMS

Schwannoma

EPIDEMIOLOGY The peak incidence of schwannomas is in the third to sixth decades. Men and women are affected similarly. Schwannomas occur sporadically or in association with neurofibromatosis type 2 (NF2), which is discussed in greater detail in Chap. 142.

ETIOLOGY AND PATHOGENESIS Schwannomas are also called *neurinomas*, *neurolem(m)omas*, or *neurilem(m)omas*. Mutations in the NF2 gene are the underlying cause of the schwannomas of both the sporadic type and NF2. They usually arise in cranial nerves, especially the vestibular nerve (the so-called *acoustic neuromas* are actually schwannomas of the vestibular division of the eighth cranial nerve); they also occur in other peripheral nerves and spinal roots.

BENIGN NERVE SHEATH NEOPLASMS AT A GLANCE



- Schwann cells and the endo- and perineurial fibroblasts make up the nerve sheath.
- Schwannomas: Benign encapsulated tumors originating from the Schwann cells.
- Neurofibromas: Benign nerve sheath tumors that are proliferations of all the nerve's elements. Presentation: Usually isolated lesions, but multiple neurofibromas found in neurofibromatosis type 1 and bilateral vestibular schwannomas found in neurofibromatosis type 2.
- Treatment: If solitary, excision. Schwannomas can often be resected without sacrificing the nerve of origin, whereas resection of a neurofibroma usually requires transection of the nerve.

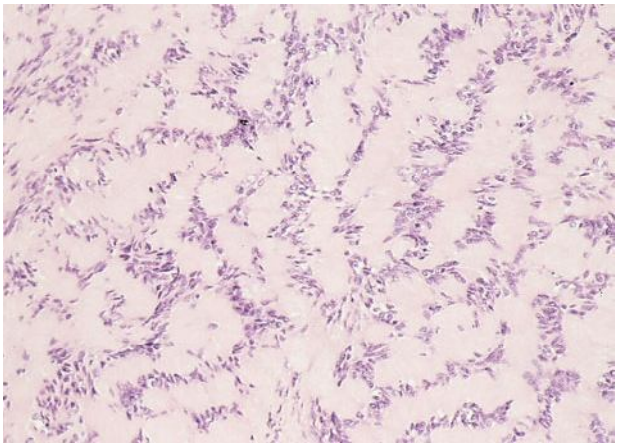
CLINICAL FINDINGS ***Cutaneous Lesions.*** The classic schwannomas often involve the head and neck. Most schwannomas are either intracranial, intraspinal, or deep soft-tissue lesions. In the skin, schwannomas present as soft, asymptomatic, dermal, or subcutaneous papules or nodules. They are usually solitary.

Multiple Schwannomas. Neurilemmomatosis or schwannomatosis presents with multiple cutaneous, soft-tissue, or spinal schwannomas, but without vestibular schwannomas or other central nervous system tumors typical of NF2 (such as meningiomas or ependymomas). This entity is usually sporadic but can rarely be familial. Some of these patients may have unrecognized NF2, either because they have had insufficient cranial imaging or because they are still too young to exclude the eventual growth of the tumors.[56] Among those in whom vestibular schwannomas have been definitively excluded, a minority carry germline mutations of the NF2 gene.[56,57] Some patients are in fact somatic mosaics, which could explain the limited extent of their disease.[58] However, the majority of schwannomatosis patients (including those with the familial form) do not have germline mutations of NF2, even though their schwannomas do harbor the typical somatic mutations seen in NF2-associated schwannomas. It has been surmised that this type of schwannomatosis is due to an inheritable predisposition to somatic NF2 mutations.[58] Finally, a last group of patients has neither germline nor somatic NF2 mutations; in these individuals, an as yet unknown gene may be involved.[55]

HISTOPATHOLOGY Because a schwannoma is a neoplastic proliferation composed only of Schwann cells and devoid of axons, it grows as an eccentric nodule, displacing its nerve of origin. This growth pattern and its cellular composition distinguish schwannoma from neurofibroma (Fig. 127-6).

Schwannomas are well encapsulated. The capsule is derived from the epineurium of the schwannoma's nerve of origin. The tumor cells are typically slender, spindled, elongated, and "wavy" in appearance. Areas of high cellularity (called *Antoni A*) alternate with areas of hypocellularity (*Antoni B*), which can have a myxoid quality. In the cellular Antoni A areas, adjacent cells have a tendency to align, creating stacks of nuclei known as *palisades*. These palisades are separated by an anuclear area made up of stacked cytoplasmic extensions; these stacks of nuclei and cell processes form the so-called *Verocay bodies* (see Fig. 127-6). Tumor blood vessels are characteristically thick and hyalinized.

By immunohistochemistry, schwannomas are strongly positive for S100 protein and negative for EMA and smooth muscle markers (desmin, α-actin), which distinguishes them from perineuromas (S100 negative, EMA positive, desmin and α-actin negative) and leiomyomas (S100 and EMA negative,



▲ **FIGURE 127-6** Photomicrograph of a schwannoma showing orderly arrangement of tumor cells into palisades and Verocay bodies. (Hematoxylin and eosin, ×100.)

desmin and α-actin positive) (see Table 127-1).

Several histologic variants of schwannoma are recognized.[59] Some tumors have extensive degeneration with cyst formation, old hemorrhage, and marked hyalinization (ancient schwannoma). This may be accompanied by bizarre nuclear morphology that does not imply malignancy. Other schwannomas are cellular with few hypocellular areas and few palisades or Verocay bodies. These tumors have been called *cellular schwannomas*.[60] They may have significant mitotic activity but behave in a benign fashion. A rare and unusual variant is the melanotic schwannoma and contains concentrically lamellated microcalcifications called *psammoma bodies*. Although this psammomatous melanotic schwannoma only rarely involves the skin, it is noteworthy that roughly one-half the affected patients have Carney syndrome (myxomas, spotty hyperpigmentation, endocrine overactivities, schwannomas)[50] and approximately 10 percent of cases metastasize.[61]

The plexiform schwannoma is a tumor that grows within a nerve, forming an agglomeration of small nodules and interconnected cords. Plexiform schwannomas have a distinct predilection for the dermis and subcutaneous tissue. The relationship between plexiform schwannoma and NF is somewhat ill-defined, because of confusing nomenclature and because some authors do not distinguish between NF1 and NF2. Some solitary, and, especially, multiple plexiform schwannomas can be associated with NF2.[62,63]

DIFFERENTIAL DIAGNOSIS Differential diagnosis of schwannomas includes lipoma, cyst, leiomyoma, and malignant peripheral nerve sheath tumor (MPNST).

TREATMENT Malignant transformation of classic schwannomas is exceedingly rare but has been reported. Excision is the treatment of choice. Plexiform schwannomas may recur, but this probably reflects incomplete excision due to their multifocal nature rather than true recurrence. Pregnancy does not alter the natural history of schwannomas.[64]

Neurofibroma

EPIDEMIOLOGY Neurofibromas often occur as solitary lesions and are common in the general population. NF1 has a prevalence of 1 in 4000.[65]

ETIOLOGY AND PATHOGENESIS Neurofibromas are hyperplasias of all the nerves elements.[66] Neurofibromas can be seen as sporadic lesions or in the context of NF1, which is covered in detail in Chap. 142. The gene for NF1 is located on the long arm of chromosome 17 (17q11.2). At least one of the functions of the NF1 protein, neurofibromin, is regulation of the *ras* oncogene.[67–69] Although it has been shown that ablating NF1 in mice can lead to the development of neurofibromas,[70] the effects on the levels of *ras* are not consistent and, thus, other stromal or genetic effects must contribute to the development of neurofibromas.

CLINICAL FINDINGS Cutaneous neurofibromas present as protuberant to pedunculated, flesh-colored, soft papules or nodules. They are usually asymptomatic, but they can be pruritic. Subcutaneous neurofibromas are usually larger than dermal lesions and consist of a fusiform swelling involving a larger nerve. In patients with NF1, the tumors start appearing in early childhood and may be quite variable in size. NF1 has a highly variable expressivity, even among patients from the same kindred who have identical germline mutations.[71] Another type of neurofibroma is the plexiform variant (Fig. 127-7), which involves an entire large nerve and its branches (see eFig. 127-7.1 in on-line edition), forming a mass of tangled, rope-like structures that feel similar to a "bag of worms" on palpation and can be associated with massive soft-tissue overgrowth, leading to functional impairment.

HISTOPATHOLOGY Histologically, a neurofibroma is composed of Schwann cells, fibroblasts, endothelial cells, perineurial fibroblasts, mast cells, and axons, all arranged haphazardly in a matrix that contains collagen and myxoid ground substance in various proportions (see eFig. 127-7.2 in on-line edition). Dermal neurofibromas are circumscribed but unencapsulated nodules. A rare sub-type of neurofibroma is the diffuse variant that involves the skin and subcutaneous tissue in a plaque-like fashion, surrounding rather than displacing pre-existing structures such as skin appendages. Plexiform neurofibromas have the same histologic appearance as ordinary neurofibromas but involve an entire nerve and its branches; they also infiltrate the surrounding soft tissue. A variant with a very unusual histologic appearance has been described as *dendritic cell neurofibroma with pseudorosettes*.[72] Finally, some neurofibromas are melanotic.

DIFFERENTIAL DIAGNOSIS Differential diagnosis of neurofibroma includes fibrolipoma, lipoma, and MPNST.

TREATMENT Solitary dermal neurofibromas can be excised. Management of patients with NF1[73] and is discussed in Chap. 142. Resection is currently the best treatment option for plexiform neurofibromas; however, the lesions frequently recur after resection. Recurrence is more commonly associated with a young patient age, incomplete tumor resection, or non-extremity tumor location.[74]

Neurothekeoma/Nerve Sheath Myxoma

EPIDEMIOLOGY The classic nerve sheath myxoma occurs in middle-aged adults with a female-male ratio of 2:1. Cellular

▲ **FIGURE 127-7** Plexiform neurofibroma on the arm. The excoriations show the pruritus associated with these lesions. (Photo from the collection of Dr. Amy Paller, MD, Children's Memorial Hospital, Chicago, IL.)

neurothekeoma most commonly occurs in younger adults.[75–77] This lesion has also been reported in children.[78]

ETIOLOGY AND PATHOGENESIS Neurothekeoma can be found in the literature under several different names such as *nerve sheath myxoma, benign myxoid tumor of nerve sheath, perineurial myxoma, bizarre cutaneous neurofibroma,* and *pacinian neurofibroma*. The last two names are actually misnomers. Two large series established it as an entity.[79] Nerve sheath myxomas consist of Schwann cells and perineural cells in a myxoid stroma. Variants of nerve sheath myxoma that are more cellular and lack the myxoid matrix have been reported as *cellular neurothekeoma*, but these tumors often lack evidence of nerve sheath differentiation and may be more closely related to fibrohistiocytic tumors.[79,80]

CLINICAL FINDINGS ***Cutaneous Lesions.*** These tumors arise in the dermis of the head, neck, shoulder, or arm where they present as nondescript, asymptomatic papules or nodules. The most common locations are the upper extremity (33.6 percent), the head and neck (29.4 percent), and the trunk (17.2 percent).[78]

HISTOPATHOLOGY The "classical" nerve sheath myxoma is hypocellular, very myxoid, and has a distinctly lobulated growth pattern. These tumors are S100 positive with immunohistochemical evidence of nerve sheath derivation (see Table 127-1).[79] They usually stain negatively for EMA. The tumor expands the dermis, leaving a grenz zone. Several cases of neurothekeomas have been reported that stain negatively for S100, and these tumors have been called *myxoid cellular neurothekeomas*.

Typical cellular neurothekeomas do not express the Schwann cell marker, S100, or the perineural marker EMA but they stain positively for CD57 and the monocyte marker Ki-M1p (see Table 127-1).

DIFFERENTIAL DIAGNOSIS Differential diagnosis of neurothekeomas includes cyst, fibrolipoma, dermatofibroma, dermal nevus, neurofibroma, neuroblastoma, and leiomyoma.

TREATMENT Neurothekeomas are clinically benign, and there is no recurrence after complete excision, but incomplete excision may result in recurrence.

Perineuroma

EPIDEMIOLOGY These are uncommon benign tumors and, due to the limited reports, epidemiologic data are scarce. Cutaneous and soft-tissue perineuriomas have a female-male ratio of 2:1.

ETIOLOGY AND PATHOGENESIS Perineurial cells form a sheath for peripheral nerves. A perineurioma is a benign peripheral nerve sheath tumor composed of cells that stain positive for EMA and negative for S100 and neurofilament (see Table 127-1).

Neither intra- nor extraneural perineuriomas appear to be associated with NF1 or NF2, but chromosome 22 deletions have been seen.[82,85,87]

CLINICAL FINDINGS There are two forms of perineurioma. One is intraneural and presents as a fusiform swelling of a major nerve, often with signs of mononeuropathy. The other form of perineurioma is extraneural. It usually arises in soft tissue, but, recently, cutaneous examples are increasingly being reported. Cutaneous perineuriomas present as flesh-colored, superficial nodules ranging in size from 4 to 14 mm. Soft-tissue perineuriomas tend to be larger and have been reported up to 58 mm in

size.[81] Perineuriomas are most commonly reported on the leg or trunk; however, sclerosing perineuriomas most commonly present on the hand.

HISTOPATHOLOGY Histologically, the intraneural perineurioma is confined to the nerve and composed of very delicate, elongated spindle cells that grow around axons, forming whorls composed of multiple concentric layers.[82] These whorls are similar to the "onion bulbs" seen in certain types of hypertrophic neuropathy. In the older literature, intraneural perineurioma is often called *localized hypertrophic neuropathy*. The cells in perineurioma clearly differentiate along perineurial lines, as shown by ultrastructure and immunohistochemistry,[82] whereas the "onion bulbs" of hypertrophic neuropathy are composed of Schwann cells. Cytogenetic evidence indicates that intraneural perineurioma is a true neoplasm. Immunohistochemistry[81,83–86] indicates perineurial differentiation (see Table 127-1).

DIFFERENTIAL DIAGNOSIS Differential diagnosis of perineurioma includes dermal nevus, dermatofibroma, and infundibular cyst.

TREATMENT Excision is curative.

MALIGNANT TUMORS OF NERVE

Malignant Nerve Sheath Tumors

EPIDEMIOLOGY Only 2 percent of nerve sheath tumors are MPNSTs.[88] Depending on the series, approximately 20 percent to 70 percent of MPNSTs occur in patients with NF1.[69] Young and middle-aged adults are most commonly affected.

ETIOLOGY AND PATHOGENESIS MPNST is also known as *neurofibrosarcoma*, *neurogenic sarcoma*, *neurosarcoma*, and *malignant schwannoma*, but because its histogenesis is uncertain, the noncommittal term *MPNST* is preferred. Plexiform neurofibromas and neurofibromas involving medium-sized to large nerves can undergo malignant degeneration into MPNSTs. Benign schwannomas and cutaneous neurofibromas, on the other hand, almost never undergo malignant transformation. There have been very few cases reported.[89]

CLINICAL FINDINGS These neoplasms arise mostly in the deep, soft tissues as nodules. Primary cutaneous MPNSTs are rare.[90,91]

HISTOPATHOLOGY MPNSTs often have a relatively non-specific presentation of interlacing bundles of spindle cells. Most tumors consist of perineural or endoneural fibroblasts.[92] Often, the major reason for calling such a tumor MPNST is that it arises within a nerve or a neurofibroma and shows some immunoreactivity for S100 protein.[93] In addition to S100 staining, MPNSTs can also stain for neuron-specific enolase, neurofilament protein, and myelin basic protein, although staining can be very weak (see Table 127-1). Cytokeratin stains are negative. MPNSTs can contain heterologous components such as bone, cartilage, glandular or squamous epithelium, and skeletal muscle. An MPNST with a rhabdomyosarcomatous component is called a *malignant triton tumor* and stain positive for myoglobin. In some MPNSTs, the tumor cells have an epithelioid appearance, and this variant must be distinguished from melanoma.[94]

DIFFERENTIAL DIAGNOSIS Differential diagnosis of MPNSTs includes neurofibroma, lipoma, and cyst.

TREATMENT MPNSTs in patients with NF are aggressive tumors with a tendency to recur and metastasize. Treatment is surgical. Outcome is guarded with reported 5-year survival rates of no more than 50 percent in spite of aggressive therapy.[69] Primary cutaneous MPNSTs may have a better prognosis.[90,91]

MALIGNANT NERVE SHEATH TUMORS AT A GLANCE

- Malignant nerve sheath tumors are also known as *neurofibrosarcoma*, *neurogenic sarcoma*, *neurosarcoma* or *malignant schwannoma*.
- Two percent of nerve sheath tumors are malignant peripheral nerve sheath tumors.
- Twenty percent to seventy percent of malignant peripheral nerve sheath tumors occur in neurofibromatosis type 1.
- Clinical presentation: Nodules in the deep soft tissues.
- Treatment: Surgical.
- Outcome: Guarded, with 5-year survival rates of not more than 50 percent.

Primitive Neuroectodermal Tumor

MISCELLANEOUS TUMORS

Granular Cell Tumor

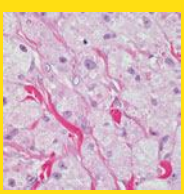
EPIDEMIOLOGY GCTs are rare. The age range at presentation is usually from the second through the sixth decades.[100]

ETIOLOGY AND PATHOGENESIS GCTs may also be referred to as *Abrikossoff tumors*. GCTs are neoplasms of uncertain histogenesis, but due to the S100 staining, current opinion favors neural crest origin.[101] The etiology is unknown, but they have been attributed to chronic trauma.[100]

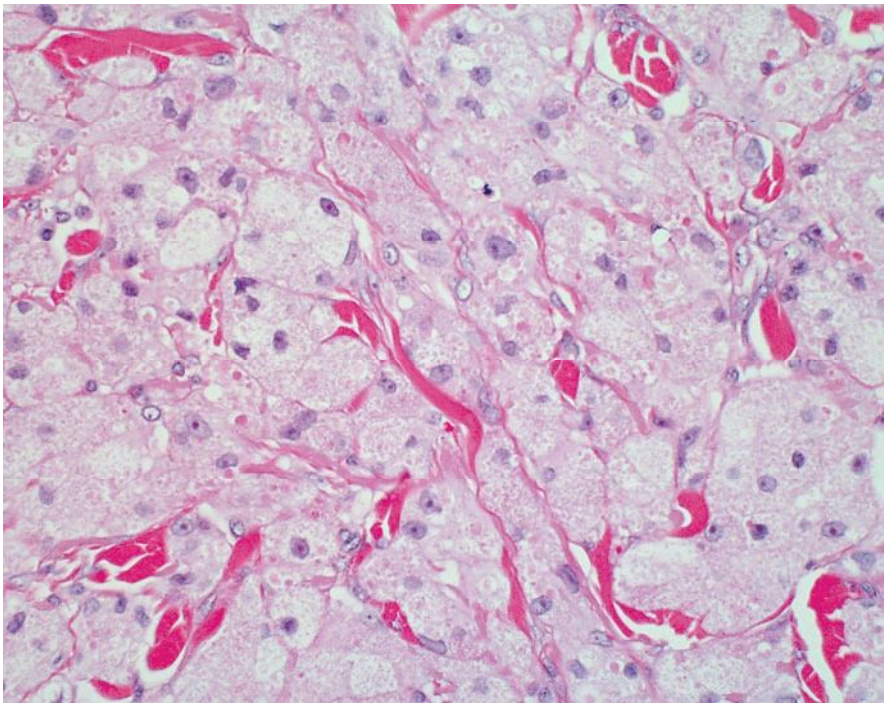
CLINICAL FINDINGS GCTs have been reported in many anatomic sites but are most often seen in the tongue and skin. The tongue is the most common single anatomic site reported; however, 44 percent of GCTs occurred in skin or subcutaneous tissue. GCTs have also been reported in the breast, genitalia, esophagus, and larynx.[100] Multiple GCTs are seen in approximately 10 percent to 25 percent of affected patients.[101] Most cutaneous GCTs are asymptomatic papules or nodules smaller than 3 cm in diameter.

HISTOPATHOLOGY The classical histologic picture is that of an ill-defined, dermal, non-encapsulated nodule composed of large, polyhedral cells that grow in a sheet-like fashion. The cells have distinct cell borders, small, round, central nuclei,

GRANULAR CELL TUMOR AT A GLANCE



- S100 positive; suspected to be of neural crest origin.
- Most common single anatomic site: Tongue.
- Forty-four percent occur in skin.
- Treatment: Excision.



▲ **FIGURE 127-8** Histologic examination of granular cell tumor. The cells have distinct cell borders; small, round, central nuclei; and abundant granular cytoplasm. (Hematoxylin and eosin, ×400.)

and abundant granular cytoplasm (Fig. 127-8). The cytoplasmic granules stain strongly with the periodic acid-Schiff stain and retain this characteristic after diastase digestion. By immunohistochemistry, the granular cells are strongly positive for S100 protein (see Table 127-1; see eFig. 127-8.1 in on-line edition). Ultrastructurally, the granules consist of phagolysosomes containing granular and membranous debris.[101] An unusual plexiform variant has been described.[101] Cutaneous and mucosal lesions typically have pseudoepitheliomatous hyperplasia of the overlying epithelium.

Only 1 percent to 2 percent of GCTs are malignant.[101] Clinical findings that should raise concern are a size larger than 4 to 5 cm, location in deep soft tissue, and recurrence. Histologic warning signs are the presence of increased cellularity, cytologic atypia, and especially mitotic figures and necrosis. However, some clinically malignant GCTs were small and/or histologically innocuous.[101] Therefore, the only definite proof of malignancy is metastasis. Other malignant cutaneous tumors that can contain a subpopulation of cells with granular cytoplasm, such as leiomyosarcoma, melanoma, or angiosarcoma have to be excluded pathologically.

DIFFERENTIAL DIAGNOSIS Differential diagnosis of GCTs includes squamous cell carcinoma of the tongue, leiomyosarcoma, melanoma, and angiosarcoma.

TREATMENT Excision is the treatment of choice.

Central Nervous System Heterotopia

Central nervous system heterotopias are composed of ectopic neural tissue and are divided into neuroglial heterotopia ("nasal glioma") and meningeal heterotopia (MH).

NEUROGLIAL HETEROTOPIA ***Epidemiology.*** Heterotopic neuroglial tissue or nasal gliomas are rare congenital lesions.[103]

Etiology and Pathogenesis. Neuroglial heterotopias represent displaced mature neuroglial tissue that is entrapped in dural diverticula. This occurs during craniofacial development and sometimes does not regress. These lesions are now considered malformations[104] rather than neoplasms, as the designation *nasal glioma* implies.

Clinical Findings. Heterotopic neuroglial tissue occurs as a solitary, firm, papule, often vascular appearing, most commonly in or on the nose but can also be present on the face, scalp, lip, tongue, oro- and nasopharynx, or orbit.

Histopathology. There are various admixtures of neurons, astrocytes, oligodendrocytes, ependyma, and choroid plexus. There may be significant fibrosis, which can obscure the neuroglial component.[104,105]

NEUROGLIAL HETEROTOPIA AT A GLANCE

- Rare congenital lesion commonly referred to as *nasal glioma*.
- Developmental anomaly consists of mature displaced neuroglial tissue; not a true neoplasm.
- Presentation: Most commonly as round, firm papule on the nose.
- Rarely connected to intracranial cavity.

Differential Diagnosis. Differential diagnosis of neuroglial heterotopia includes encephalocele, dermoid cyst, hemangioma, intracranial astrocytoma or meningioma with nasal extension, lymphatic malformation, lymphoma/plasmacytoma, and carcinoid tumor.

Prognosis and Clinical Course. Neuroglial heterotopias can be connected to the intracranial cavity, and therefore computed tomography and/or magnetic resonance imaging of the head is imperative before biopsy or excision. In one small series, three of 10 patients had lesions that extended into the intracranial cavity.[106]

Treatment. Surgical excision is the treatment of choice.

MENINGEAL HETEROTOPIA ***Epidemiology.*** Heterotopic meningeal tissue is a rare condition that presents most commonly in the neonatal period but can also be seen in adults. Rare familial cases have been reported.[107,108]

MENINGEAL HETEROTOPIA AT A GLANCE

- Rare lesion characterized by meningothelial elements in skin.
- Occurs in children secondary to developmental defect; occurs in adults secondary to extension of intracranial meningioma.
- Can be connected to intracranial cavity.

Etiology and Pathogenesis. MH is characterized by meningothelial elements present in the skin.[107] This condition is also known as *cutaneous meningioma, rudimentary meningocele, acroleic meningocele,* and *meningeal hamartoma*. In adults, these lesions usually represent cutaneous or subcutaneous extension of an aggressive intracranial meningioma and are commonly referred to as *cutaneous meningiomas*. In children, they are often referred to as *rudimentary meningoceles* and most likely represent a developmental defect related to abnormal attachment and closure of the neural tube during embryogenesis. There is evidence to suggest that rudimentary meningoceles represent an atretic form of a meningocele.[107] Some lesions may contain a central lumen and be connected to the dura by a fibrous band running through a skull or vertebral defect.

Clinical Findings. MH typically presents as a skin-colored nodule on the scalp over the midline or along the spine. In children, they can be associated with the "hair collar" sign, in which a ring of long, dark, coarse hair surrounds a midline scalp nodule. In adults with cutaneous meningiomas, the intracranial component itself may surprisingly cause few neurologic symptoms, and patients may actually present because of an enlarging nodule on their scalp.

Histopathology. Microscopic examination reveals a mass composed of meningothelial elements in the superficial and deep dermis surrounded by dense collagen bundles.[107] The meningothelial cells contain round nuclei with stippled chromatin and clear cytoplasm.[108] Occasionally, a whorled pattern can be observed. Psammoma bodies, collagen bodies, and calcification are variably present.[107,108]

Differential Diagnosis. Differential diagnosis of MH includes meningocele, encephalocele, aplasia cutis, and epidermal/pilar cyst.

Prognosis and Clinical Course. These lesions can be connected to the intracranial cavity, and, therefore, radiographic imaging is necessary before any invasive procedure such as biopsy or excision.

Treatment. The treatment of choice is surgical excision.

CHAPTER 128

Kaposi Sarcoma

Erwin Tschachler

In 1872, the Austro-Hungarian dermatologist Moriz Kaposi described five patients with multicentric cutaneous and extra-cutaneous neoplasm that primarily affected older individuals.[1] This disease, originally described as *idiopathic multiple pigment sarcoma*, was later eponymously designated Kaposi sarcoma (KS). Since then, different variants of this tumor have been described, which have distinct epidemiologic features and run distinct clinical courses but show comparable histopathologies.

ETIOLOGY AND PATHOGENESIS

Human Herpesvirus-8 and Kaposi Sarcoma

Several decades of epidemiologic data and electron microscopic studies have suggested the involvement of an infectious agent in the etiology of KS.[2,3] This suspicion was substantiated in 1994 when Chang and colleague discovered DNA of an unknown virus in KS lesions.[4] This discovery led to cloning, isolation, and characterization of a novel human herpesvirus now referred to as *Kaposi sarcoma-associated herpesvirus* (KSHV) or alternatively, human herpesvirus (HHV)-8.[5,6]

HHV-8 is a member of the γ-herpesviridae subfamily, genus rhadinovirus.[5–9] Its 165-kb DNA genome has been entirely sequenced and shown to contain approximately 90 open reading frames.[6–8] Many of the HHV-8 regulatory genes are homologous to genes of other rhadinoviruses, and several are homologous to human genes involved in regulation of apoptosis, cell proliferation, and angiogenesis.[6,9,10] As in other herpesviruses, HHV-8 gene expression is tightly controlled and either associated with viral latency such as LANA-1, V cyclin and vFLIP or lytic viral replication such as vGPCR, vIL 6, and v-bcl-2.[6,10] Several HHV-8 gene products, both of the lytic and the latent viral life cycles, have been shown to transform cells in vitro as well as in animal models in vivo.[6,10–13] It is therefore generally accepted that HHV-8 is a transforming herpesvirus[7] and that this capacity plays a direct role in the development of KS.

The host range of HHV-8 in vivo and in vitro comprises vascular and lymphatic endothelial cells as well as different types of hemopoietic cells.[5] The widely expressed 12-transmembrane light chain of the human cystine/glutamate exchange transporter system xc– has recently been put forward as fusion entry receptor of HHV-8.[14] Other surface molecules such as $\alpha_3\beta_1$ integrin and heparan sulphate proposed earlier to allow for HHV-8 infection appear to play only a secondary role.[15] However, because peripheral blood $CD19^+$ B cells, which are permissive for infection in vitro, appear not to express the cystine transporter xCT[14] other receptor molecules are likely to be identified in the future.

The routes of HHV-8 transmission are not completely known. The high number of KS in homosexual and bisexual men and the association of tumor development with certain sexual practices early on suggested the sexual transmis-

KAPOSI SARCOMA AT A GLANCE

- Multifocal, systemic tumor of endothelial cell origin with stage-dependent characteristic histopathology.
- Four clinical variants:
  - Classic Kaposi sarcoma (KS)—in old men, starts as localized form, progresses slowly.
  - Endemic African KS—most frequent neoplasm in some central African countries; includes a rapidly progressive lymphadenopathic variant.
  - KS associated with immunosuppressive therapy—most frequently in organ transplant recipients.
  - Acquired immunodeficiency syndrome (AIDS)-related KS—rapidly progressive form with early systemic involvement, predominantly in bisexual and homosexual AIDS patients.
- Invariably linked with human herpesvirus-8 infection.
- Responds well to chemo- and radiation therapy.

sion of the virus.[3] In later epidemiologic studies sexual activities were confirmed as a route for HHV-8 transmission and it was demonstrated that the transmission risk increases with the increase of numbers of sexual partners[16] and participation in certain forms of oral/genital and oral/anal sex.[16,17] By contrast, in areas where the virus is widespread, such as in Mediterranean countries and in Africa, strong evidence exists that nonsexual transmission among family members[16] plays a major role. The oropharynx is the site of strongest viral replication and high HHV-8 copy numbers are present in saliva.[18] Based on these findings, the nonsexual transmission via saliva is widely assumed to play the most important role in childhood transmission in endemic areas.[19] Vertical transmission from mother to child during pregnancy or birth seems not to play an important role for the spread of the virus.[16] For the medical profession, it is important to remember that HHV-8 may also be transmitted by blood and blood products as well as from donor organs in the course of transplantations.[16,20]

HHV-8 is present in all KS variants[21,22] and the evidence for a causal relationship between HHV-8 infection and KS tumor development is overwhelming. Among the most important arguments for a role of HHV-8 in KS pathogenesis are the findings that (1) the HHV-8 viral genome is detectable in KS lesions of all stages regardless of the clinical variant;[5,6,21,22] (2) within KS lesions HHV-8 is present in latent form in virtually all tumor cells;[23,24] and (3) KS tumor cells show monoclonal integration of viral DNA.[5,6] Furthermore, the prevalence of HHV-8 infection is largely congruent with that of KS: In areas of low incidence of KS, such as the United States and Northern Europe, HHV-8 infection is very rare (below 0.1 percent).[16,25] By contrast, in areas where high incidence of KS has been reported, such as in Southern Italy, HHV-8 prevalence is much higher and approaches 20 percent.[16,26] As expected, the highest HHV-8 prevalence has been found in central Africa in the regions known to be hotspots of African endemic KS. In this region, the seroprevalence in adults ranges from 22 percent to 71 percent.[16] Similarly, in human immunodeficiency virus (HIV)-1–infected patients in developed countries, HHV-8 prevalence is highest in homosexual and bisexual men and reflects the incidence of KS in this risk group.[16,27]

The time span from infection with HHV-8 to development of KS depends on the clinical type. Immunosuppression/dysregulation plays an important aggravating role and leads to disease manifestation in organ transplant recipients within 1 to 2 years and in HIV-1 infected patients 5 to 10 years after infection.[16] For classic KS this time span is far longer and the contributions of either host or environmental factors are not yet established.[16]

In addition to KS, HHV-8 has been implicated in the pathogenesis of pleural effusion lymphoma, a rare B cell neoplasm seen primarily in acquired immunodeficiency syndrome (AIDS) patients, and multicentric Castleman disease (MCD).[5,6,10,16] In the former, HHV-8 is invariably present and diagnostic, in the latter it is found in the majority (> 95 percent) of HIV-infected patients with MCD but only in approximately 40 percent of HIV-negative MCD patients.[10] MCD has been associated in the past also with classic KS.[28]

Histogenesis

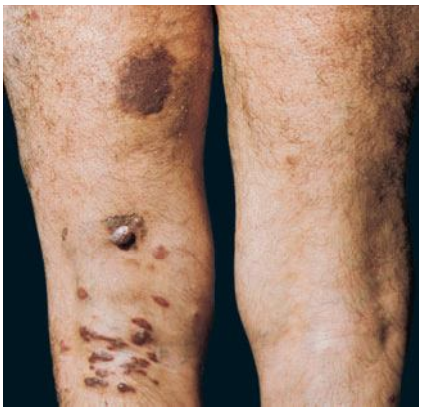
The histogenetic derivation of the KS tumor cells (i.e., the cells lining the irregular vascular-like spaces of early and angiomatous lesions and the cells composing the bundles and interlacing fascicles of solid tumors) has been the subject of intense research over the past two decades. The immunophenotype of these cells (i.e., vWF$^{+/-}$, PAL-E^{-}, CD31^{+}, CD34^{-}, VEGFR3^{+}) characterizes them as part of the lymphatic endothelial differentiation lineage.[29,30] The recent demonstration that HHV-8 replicates better in lymphatic than in blood vascular endothelial cells is a further argument for this assumption.[31] However, the finding that infection of blood vascular endothelial cells with HHV-8 leads to a phenotypic switch towards lymphatic endothelial cells[31,32] leaves the possibility that an immature angioblast either resident in the skin or circulating and able to differentiate into both endothelial cell lineages is the initial precursor of KS tumor cells.[33,34]

Some controversy also surrounds the question of whether KS is a reversible proliferative disorder or a true malignant neoplasm. Analyses of the methylation pattern of the human androgen receptor gene have shown that lesions with both clonal and polyclonal proliferations can be identified.[5,35,36] Moreover, multiple lesions that arise in an individual patient may develop independently from distinct transformed cells and later acquire clonal characteristics.[5] Studies of HHV-8 terminal repeat sequences which show monoclonality in nodular KS lesions support these findings[37] and indicate that KS starts as a polyclonal disease with subsequent evolution to a monoclonal process.[5]

Classic Kaposi Sarcoma

EPIDEMIOLOGY The annual incidence rates for classic KS vary greatly in different geographic regions and ranges from 0.14 per million inhabitants (for both women and men) in Great Britain to 10.5 per million in men and 2.7 per million in women in Italy.[38] A preponderance of male patients has existed since the original description and a male-female ratio of approximately 3:1 is found in large surveys of most regions.[38,39] The higher KS incidence in countries surrounding the Mediterranean has led some authors to speak of a Mediterranean KS variant as a distinct entity.[40] However, because the clinical course is comparable to that of classic KS, Mediterranean KS is not treated separately here.

▲ **FIGURE 128-1** Classic variant. Plaques and papules localized on the dorsum of the foot, a site of predilection of classic Kaposi sarcoma.



▲ **FIGURE 128-2** Tumor nodules of more advanced classic Kaposi sarcoma (Mediterranean variant) with severe involvement of extremities.

CLINICAL MANIFESTATIONS The typical patient with classic KS is a Caucasian male in his sixties with a Mediterranean or Jewish background. The tumors usually start on the skin of the distal portions of the lower extremities as unilateral or bilateral bluish-red (hematoma-like) macules. These lesions tend to progress slowly both horizontally and vertically and develop into firm plaques (Fig. 128-1) and, eventually, into nodules. During tumor progression the color changes to brownish and the skin overlying the tumor becomes hyperkeratotic and, in particular on the lower extremities, may ulcerate. Surrounding the tumor there is frequently a pitting edema which may evolve into fibrosis. Classic KS usually runs a rather benign course slowly extending proximally and patients may sometimes live with slowly progressive disease for decades.[38,39,41] After several years of progression (Fig. 128-2), dissemination to other body sites is frequently seen, and tumors may become manifest in lymph nodes, on mucous membranes, and in internal organs such as the gastrointestinal tract where it is rarely symptomatic.[41,38] Because classic KS affects mostly elderly patients, death from other causes may precede its full spread.

African Endemic Kaposi Sarcoma

EPIDEMIOLOGY An increased frequency of KS in black Africans in Central Africa was noted several decades before the outbreak of the AIDS pandemic.[42–44] In some countries of this region, KS accounts for up to 10 percent of all malignancies in men.[5,16,42,43] A prevalence of male patients, with male-female ratios ranging from 3:1 in children and up to 18:1 in adults is seen with endemic African KS.[38] The age at onset is lower than that in classic KS at 35 to 39 years for males and 25 to 39 years for females.[38]

CLINICAL MANIFESTATIONS African-endemic KS occurs as nodular, florid, infiltrative, and lymphadenopathic types.[45,46] The florid/vegetating and infiltrative variants are characterized by a more aggressive biologic behavior and lesions extend deeply into the dermis, subcutis, muscle, and bone. Lymphadenopathic African KS predominantly affects children and young adults and may follow a fulminant course with rapid progression.[47] Skin and mucosa are affected to a lesser degree. The reasons for the different courses observed in African KS are not clear and potential co-factors have not been unequivocally identified.

Kaposi Sarcoma in Therapeutically Immunosuppressed Patients

EPIDEMIOLOGY During the 1970s, a high incidence of KS was described in organ-transplant recipients receiving immunosuppressive therapy (up to 500-fold increased as compared to the control population).[48,49] Transplantation-associated KS is observed predominantly in kidney allograft recipients, whereas it occurs rarely in recipients of other solid organs and bone marrow allografts.[48–50] In addition to post-transplantation, KS has been reported in patients receiving immunosuppressive therapy for other reasons, most notably the treatment of autoimmune diseases.[51–53]

The clinical appearance and the course of KS in therapeutically immunosuppressed patients may be slowly progressive as with the classical variant but can also be rapidly disseminating like in AIDS KS (see the section Clinical Manifestations). KS can occur from 1 month to more than 10 years after transplantation.[54] The dose and type of the immunosuppressive drug are very important risk factors for developing KS and determining its clinical course.[40,50] For example the risk of KS associated with cyclosporin A is higher than with other drugs, such as glucocorticoids and azathioprine, and the disease onset is earlier.[49,50] Regression of KS can be achieved by reduction or withdrawal of the immunosuppression (see the section Clinical Manifestations). Conversely, rapid tumor progression can occur after dosage increase.[49,50] In transplantation-associated KS, a preponderance of male patients, with a ratio of approximately 3:1 is observed[50] and in geographic regions with a high incidence of classic KS as well as in ethnic groups with a higher risk KS development, the risk for transplantation associated KS is increased.[50]

CLINICAL MANIFESTATIONS Skin lesions of KS in this group of patients are identical to those of classic and HIV-associated KS. In a large series, skin involvement was found in more than 85 percent of patients with transplantation-associated KS whereas less than 15 percent had visceral disease (gastrointestinal, lungs, lymph nodes) without skin involvement.[50]

AIDS-Associated Kaposi Sarcoma

EPIDEMIOLOGY A major harbinger of the AIDS pandemic were clusters of young homosexual men suffering from KS in large U.S. cities in 1981.[55] During the first decade of the AIDS pandemic, KS had been diagnosed as the AIDS-defining disease in more than 20 percent of HIV-1–infected patients in Europe.[56] Despite a decline in recent years, KS is still the most frequent AIDS-associated tumor in men who have sex with men. Other patient groups at risk for AIDS, including intravenous drug users, hemophiliacs, blood transfusion recipients, and children born to HIV-positive mothers in industrialized countries, are far less affected.[3,57] The situation is different in Africa, where KS is the most frequent tumor arising in HIV-1–infected patients independent of risk groups, including children suffering from AIDS.[58,59]

AIDS KS differs from classic KS by its more rapid course and its rapid multifocal dissemination: early AIDS-KS lesions appear as small oval violaceous macules that develop rapidly into plaques and small nodules. They are frequently present at multiple locations at

▲ **FIGURE 128-3** Acquired immunodeficiency syndrome–associated Kaposi sarcoma. Multiple lesions at all stages of development (macules, papules, nodules) are present on the trunk. Note that the lesions follow the skin's relaxed tension lines.

disease onset and have a tendency for rapid progression. In contrast to other variants of KS, the initial lesions in AIDS patients frequently develop on the face, especially on the nose, eyelids, and ears, and on the trunk, where the lesions follow the relaxed skin tension lines (Fig. 128-3). If untreated, disseminated AIDS-KS lesions may coalesce to form large plaques involving large areas of the face, the trunk, or extremities and lead to functional impairments. The oral mucosa is frequently involved and represents the presenting site in 10 percent to 15 percent of AIDS KS (Fig. 128-4). Involvement of the pharynx is not uncommon and may result in difficulty eating, speaking, and breathing.[60]

Involvement of extra-cutaneous sites occurs more rapidly and more dramatically in patients with AIDS KS than in those with classic KS. In addition to the oral mucosa, KS lesions are most frequently found in lymph nodes, the gastrointestinal tract, and the lungs.[61–63] Although gastrointestinal KS is usually found when cutaneous lesions are present, exclusive gastrointestinal involvement is possible. The stomach and duodenum represent predilection sites and KS lesions there can cause clinical symptoms such as bleeding and ileus. Although visible on gastroscopy, such lesions are underdiagnosed histologically because they are located in the submucosa and may escape the biopsy forceps. Pulmonary KS can cause respiratory symptoms such as bronchospasm, coughing, and progressive respiratory insufficiency.[62] Bronchoscopy with transbronchial biopsy is most appropriate for the diagnosis of pulmonary KS.

▲ **FIGURE 128-4** Kaposi sarcoma lesions on the hard palate are typical manifestations of acquired immunodeficiency syndrome–associated Kaposi sarcoma.

DIFFERENTIAL DIAGNOSIS Differential diagnoses for cutaneous KS depend on the clinical stages and are shown in Box 128-1.

Box 128-1

Clinical Differential Diagnoses of Cutaneous and Mucosal Kaposi Sarcoma

Most Likely

- Localized early disease
  - Hematoma
  - Stasis dermatitis
  - Bacillary angiomatosis
  - Pyogenic granuloma
  - Well-differentiated angiosarcoma
- Advanced disease
  - Acroangiodermatitis (pseudo Kaposi)
  - Bacillary angiomatosis
- Oropharyngeal lesions
  - Non-Hodgkin lymphoma
  - Squamous cell carcinoma
  - Bacillary angiomatosis

Consider

- Localized disease
  - Dermatofibroma
  - Melanoma
  - Dermatofibrosarcoma protuberans
  - Leiomyosarcoma
  - Kaposiform hemangioendothelioma (in children)
  - Blue rubber bleb nevus syndrome
- Advanced disease
  - Metastasizing melanoma
  - Cutaneous metastasis of internal malignancies and leukemias
  - Erythema elevatum et diutinum
  - Angiosarcoma

Always Rule Out

- HIV-1 infection
- Non-HIV-1–related causes of immunosuppression
- Melanoma

HIV = human immunodeficiency virus.

HISTOPATHOLOGY

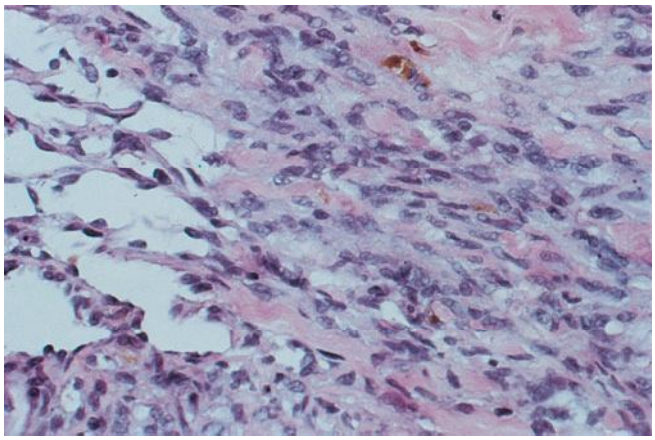
The histopathology of KS is dependent on the stage of KS development.[64–66] Early patch-like lesions exhibit rather discrete histopathologic changes, consisting mainly of an increase in the number of dermal vessels, outlined by slightly irregular endothelial cells (Fig. 128-5). These vessels, located mainly in the superficial dermis are parallel to the skin surface, are frequently slightly irregular, and may form bizarre slits and clefts. In the surrounding skin focal hemosiderin, deposits and extravasated erythrocytes can be found as well as a moderate inflammatory infiltrate. Important differential diagnoses of this stage include lymphangioma and granulation tissue.

The pathology of KS plaques is more characteristic and reveals extensive vascular proliferation at all levels of the dermis with multiple dilated and angulated vascular spaces dissecting the collagen leaving a spongy network of collagen tissue. A characteristic sign of KS papules is the presence of solid cords and fascicles of spindle cells arranged between the jagged vascular channels. This biphasic angiomatous and solid tumor morphology changes to a clear-cut sarcomatous morphology with progression of the disease.

Nodular lesions consist predominantly of spindle cells arranged in bundles and interlacing fascicles and interspersed, irregular, slit-like vascular spaces without endothelial linings. Advanced lesions may display pronounced pleomorphism, nuclear atypia, and mitotic figures. At the periphery of solid tumors, (lymph) angiomatous-like portions of KS with bizarre vascular lumina and intravascular and extravasated erythrocytes, as well as siderophages, may be preserved. Erythrocytes, which appear as eosinophilic globules, are trapped within the slits and clefts formed by the spindle cells and erythrophagocytosis are occasionally observed. As in all other stages of KS, a moderate inflammatory infiltrate consisting of lymphocytes, histiocytes, plasma cells, and, sporadically, neutrophils is regularly present.

TREATMENT

The treatment modalities for KS depend on the clinical type, the extent of the le-



▲ **FIGURE 128-5** Histopathology of Kaposi sarcoma (biopsy taken from a nodular Kaposi sarcoma lesion). Angiomatous portions, reminiscent of a lymphangioma, as well as solid, sarcomatous fascicles are present.

sions, and on the organ system involved (Box 128-2). Despite the overwhelming evidence that infection with an oncogenic herpesvirus, i.e., HHV-8 plays a central role in KS pathogenesis; antiherpetic drugs have so far been only of experimental value.[67] Because AIDS KS incidence has been much higher than that of the other clinical variants in the past decades and due to the fact that KS in AIDS patients quickly progress into a life-threatening disease, studies on AIDS KS have brought about many of the recent insights and advances in the treatment of KS.[68,69]

Localized Cutaneous Disease

Regardless of the clinical variant, if a patient presents with only limited disease confined to the skin, local therapies aimed at eliminating individual lesions are frequently used as initial treatment.[68,69] Although recurrence rates are high, local therapies may satisfactorily slow progression of classic KS for several years. By contrast, in the other clinical variants it is imperative that local therapy is supported by additional measures such as change of the immune suppressive therapy in transplantation-associated KS and initiation of highly active antiretroviral therapy (HAART) in patients with AIDS KS.

Local therapies include surgical excision,[70] local destruction with liquid nitrogen, laser or photodynamic therapy,[71] and topical therapy with 9-*cis* retinoic acid.[72] Radiation therapy[73] is useful in localized disease at sites that are difficult to reach by other local approaches such as the nose and oral mucosa. It should also be considered in more advanced KS, in particular in resource poor settings.

PROGRESSIVE CUTANEOUS DISEASES AND INVOLVEMENT OF OTHER ORGANS ***Classic Kaposi Sarcoma.*** Chemotherapy, including doxorubicin, bleomycin, vincristine, etoposide and dacarbazine, alone or in combination has been given to patients with rapidly progressive or widespread classic KS especially if internal organs are involved.[74] However, due to the low incidence of classic KS, large comparative prospective studies are not available. As in AIDS KS, liposomal anthracyclines are effective[75] and in one recent retrospective study were demonstrated superior to low dose interferon-α.[76]

Kaposi Sarcoma in Patients with Therapeutic Immunosuppression. KS in transplant patients responds well to a reduction of immunosuppressive therapy.[49,50] Recently, replacement of calcineurin inhibitors by rapamycin has led to dramatic therapeutic improvement with complete remission of advanced KS lesions.[77,78] This effect seems to be due to the modulation of the immune response by the change of therapy and to direct antitumor effects of the drug.[78] Rapamycin may therefore also be of potential benefit for treating KS in patients not receiving immunosuppressive therapy.

AIDS-Associated Kaposi Sarcoma. Until the advent of HAART, treatment of advanced AIDS KS had been mostly palliative with either combination chemotherapies or radiation therapy.[79] During the mid 1990s HAART became available and it became possible for the first time to achieve sustained suppression of HIV-1 replication and immune recovery. Subsequent to the introduction of HAART a decrease in AIDS KS incidence and frequent remission of early KS lesions were observed during therapy.[80] Besides their effects on HIV-1 replication, protease inhibitors (one drug of the combination antiretroviral therapy) have been suggested to have a direct antitumor effect and trials evaluating these drugs in HIV-negative patients with KS are currently under way.[81] However, HAART alone is not sufficient to control KS that has already advanced. Therefore, if despite successful HAART and the control of HIV-1 replication, widespread lesions and/or the involvement of organs other than the skin occurs, addition of chemotherapy is required.[82] Of the chemotherapeutic regimens used in the past, liposomal anthracyclines have been shown to be more efficient and better tolerated than combination therapies such as bleomycin and vincristine or both combined with doxorubicin (see Box 128-2).[83–85] A typical drug regimen consists of 20 mg/m^2 liposomal anthracyclines given intra-

Box 128-2

Treatment Options for Kaposi Sarcoma

Localized disease

- Local therapy
  - Surgical excision
  - Cryotherapy
  - Topical 9-*cis* retinoic acid
- Radiation therapy

Disseminated disease/internal organ involvement

- Systemic therapy
  - For patients with AIDS—initiate highly active antiretroviral therapy
  - For patients on immunosuppressive therapy—re-evaluate drug regimen
  - For AIDS patients not responding to highly active antiretroviral therapy alone—systemic cytotoxic chemotherapy
    - Liposomal anthracyclines (e.g., liposomal doxorubicin 20–40 mg/m^2 every 2–4 wk)
    - Paclitaxel (100 mg/m^2 given every 2 wk)
  - For patients with classic Kaposi sarcoma
    - Liposomal anthracyclines (e.g., liposomal doxorubicin 20–40 mg/m^2 every 2–4 wk)
    - Vinblastine (6 mg IV once a week)
    - Doxorubicin//bleomycin//vincristine (20–30 mg/m^2//10 mg/m^2//1–2 mg// every 2–4 wk)
    - Interferon-α (3 million–30 million units daily to 3×/wk)
- Investigational treatments
  - Thalidomide
  - Vascular endothelial growth factor-antisense
  - COL-3 (matrix metalloproteinase inhibitor)

AIDS = acquired immunodeficiency syndrome.

ANGIOSARCOMA AT A GLANCE

- Malignant tumor of endothelial cell origin.
- Occurs in 3 clinical variants:
  - Primary angiosarcoma (mostly affects elderly with a predilection for head, neck, and face).
  - Angiosarcoma in areas of chronic lymphedema [most frequently in patients after lymph-node dissection due to mammary carcinoma—(Stewart-Treves syndrome)].
  - Postirradiation angiosarcoma.
- Despite complete surgical excision and/or chemotherapy, prognosis of angiosarcoma is poor.
- Several very rare low-grade angiosarcomas exist:
  - Endovascular papillary angioendothelioma
  - Epithelioid hemangioendothelioma
  - Retiform hemangioendothelioma

venously every 2 to 4 weeks.[86] An advantage of the use of liposomal anthracyclines is their continued therapeutic efficacy in patients who have been previously treated by other forms of chemotherapy. For patients with anthracycline-refractory AIDS KS, paclitaxel has recently been added as potential rescue therapy.[87] Interferon-α which has been a mainstay therapeutic approach for AIDS KS during the 1980s and early 1990s still holds some promise for AIDS patients with early disseminated KS who simultaneously receive HAART.[67]

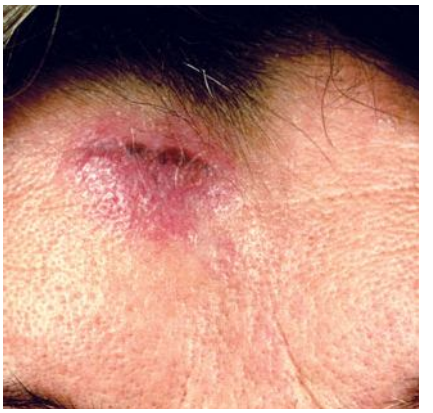
In addition to the therapies mentioned above there are several experimental therapies ranging from vascular endothelial growth factor antisense to anti-herpetic drugs currently being evaluated in clinical trials.[68]

ANGIOSARCOMA

Epidemiology and Pathogenesis

Angiosarcomas are highly malignant vascular tumors with an incidence of approximately 0.01/100,000 affecting primarily adult patients.[88] They may occur in different organs but in more than 50 percent localize to the skin of the head and neck regions.[89,90] Besides primary tumors, which appear in previously normal skin, angiosarcomas show an increased incidence in skin with chronic lymphedema, most frequently, but not exclusively, after mastectomy with lymph node dissection. This variant is also referred to as *Stewart-Treves syndrome*[91] and was formerly classified as lymphangiosarcoma. A rare variant is postirradiation angiosarcoma, which may develop after radiation therapy for mammary carcinoma.[92]

Tumor cells of angiosarcoma express to varying degrees differentiation markers of both the lymphatic and vascular endothelial cell lineage.[93] Whether common precursor cells (i.e., angioblasts) give rise to the tumor cells remains to be seen. Therefore, the designation angiosarcoma instead of either lymphangiosarcoma or hemangiosarcoma seems appropriate at the moment. In contrast to KS, angiosarcoma is usually negative for HHV-8.



▲ **FIGURE 128-6** Cutaneous angiosarcoma of the face. Early bruise-like lesions on the forehead.

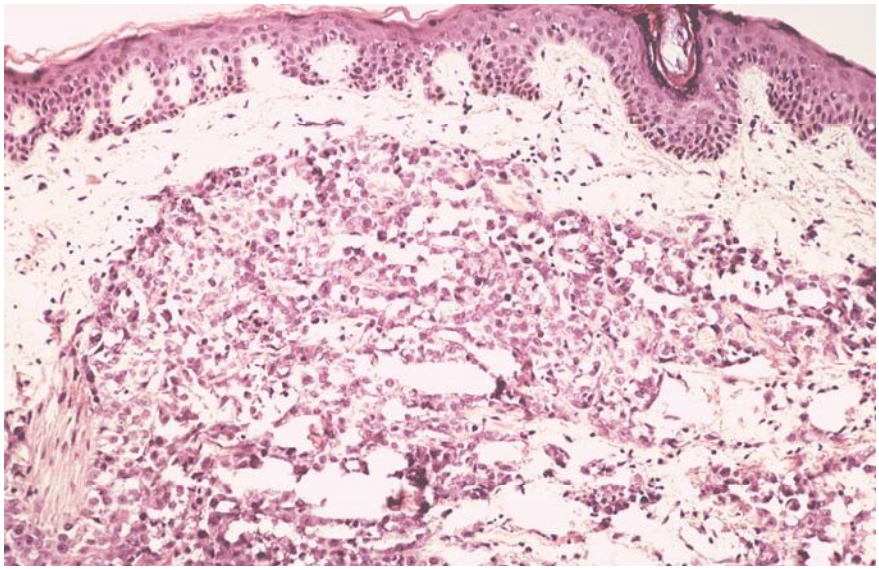
▲ **FIGURE 128-7** Cutaneous angiosarcoma of the head. Advanced lesion presenting as violaceous patch extending over the right forehead, ear, and scalp and crusted nodules in the parietal and temporoparietal regions.

Clinical Manifestations

Initially, primary angiosarcoma of the skin presents as singular or multifocal "bruise"-like patches on the skin, most frequently on the face (Fig. 128-6), scalp, or neck regions. In the "head-tilt" maneuver, where the patient lowers the head below the level of the heart, the involved skin becomes deeper red and violaceous and painful throbbing may be felt.[94] On progression, the lesions become violaceous and ill-defined spongy nodular tumors appear, which bleed easily. Horizontal spread can lead to the involvement of large skin portions (Fig. 128-7). The tu-

▲ **FIGURE 128-8** Stewart-Treves syndrome on the right forearm and hand.

▲ **FIGURE 128-9** Postirradiation angiosarcoma of the breast.



▲ **FIGURE 128-10** Histopathology of cutaneous angiosarcoma.

mor usually progresses along the vascular structures of the neck (see eFig. 128-7.1 in on-line edition) to the mediastinum but distant metastases also occur. Prognosis is poor. Angiosarcoma developing in chronic lymphedema [i.e., Stewart-Treves syndrome (Fig. 128-8) as well as post-irradiation angiosarcoma (Fig. 128-9)] arises as infiltrating hemorrhagic plaques or violaceous nodules accompanied by edema. They are also high-grade malignancies with a poor prognosis.

Differential Diagnoses

Early lesions can be confused with various skin pathologies with vascular involvement including ecchymoses, port-wine stain, rosacea, and early KS. For advanced tumors, pyogenic granuloma, lymphoma, and amelanotic melanoma, cutaneous metastasis of internal malignancies have to be considered.

HIstopathology

The different clinical variants are indistinguishable histologically and great variability with regard to differentiation of vascular elements can be seen even within individual lesions. Irregular, anastomosing vascular channels lined by endothelial cells with different degrees of atypia and mitotic activity may alternate with areas of closely packed cells with a high mitotic index and sometimes spindle-like morphology (Fig. 128-10). In the latter, less well-differentiated areas and little or no luminal differentiation is present. In particular, in these instances immunostaining for vascular markers such as CD31 and CD34 is helpful for the establishment of the diagnosis.

Treatment

Current treatment is not highly effective with an overall estimated 5-year survival of 15 percent.[90,95] Due to the rarity of angiosarcomas, comparative therapeutic trials are not available. Treatment of choice for small tumors is excision with wide margins.[95] When surgery is not an option, palliative radiotherapy or chemotherapy should be considered.[95–97] Both liposomal doxorubicin and paclitaxel were recently demonstrated to be of benefit for patients with widespread disease.[96–98] Interferon-α, although not effective by itself, holds some promise in combination with either doxorubicin or 13-*cis* retinoic acid.[99]

Rare Low-Grade Angiosarcomas

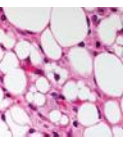
CHAPTER 129

Neoplasms of Subcutaneous Fat

Thomas Brenn

LIPOMA

- Lipoma is the most common soft-tissue tumor.
- It is benign and presents in adulthood as a small circumscribed mass. The anatomic distribution is wide with relative sparing of the head, hands, and feet.
- Histologically, the tumors are circumscribed, encapsulated, and composed of mature white adipose tissue.



Epidemiology

Lipomas are the most common soft-tissue neoplasms. Although they affect individuals in a wide age range, they occur predominantly in adults between the ages of 40 and 60 years; presentation in childhood is rare. There is no gender predilection. Lipomas are multiple in approximately 5 percent of cases.[1]

Etiology and Pathogenesis

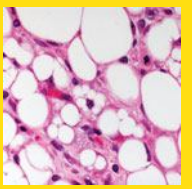
The majority of lipomas (approximately 75 percent) show karyotypic abnormalities. The cytogenetic findings are heterogeneous, but rearrangements of 12q13-15 are most common.[2–4] Other affected loci are on chromosomes 6 and 13.[2–4] Numerical abnormalities are scarce, and most tumors are diploid.

Clinical Findings

The most common presentation is as a painless, slowly enlarging mass involving the subcutaneous tissue of the trunk, neck, or proximal extremities. Involvement of the head, hands, and feet is uncommon. These superficial lipomas are typically small, measuring less than 5 cm.[1] Lipomas may be multiple and familial and show a predilection for the arms and thighs in familial multiple lipomatosis (Fig. 129-1).[5] The constellation of multiple lipomas, macrocephaly, lymphangiomas, and hemangiomas is known as *Bannayan (Bannayan-Zonana)* syndrome.[6,7] This autosomal dominant disease shares features with other independently described entities and is currently also referred to as *Bannayan-Riley-Ruvalcaba syndrome*.[8,9] Further clinical findings include intestinal polyposis, genital pigmented macules, and other hamartomas. The syndrome is caused by mutations in the PTEN gene and belongs to the larger family of PTEN hamartoma-tumor syndromes, including Cowden disease.[10–15] Lipomas may also be seen as a manifestation of Gardner syndrome. Gardner syndrome is part of the spectrum of familial adenomatous polyposis and includes extracolonic manifestations such as desmoid fibromatosis, osteomas, cysts, and lipomas.

Less frequently, lipomas may be deep-seated and grow to sizes larger than 5 cm. They can affect a variety of anatomic locations, including the surface of bone (parosteal lipoma) and skeletal muscle (intramuscular and intermuscular lipoma). Intramuscular lipoma arises within skeletal muscle and may be circumscribed or infiltrative. It presents in adulthood and only rarely affects children. The range of anatomic sites is wide, but there appears to be a predilection for the trunk.[16,17] In contrast, intermuscular lipoma develops between individual muscles and does not infiltrate skeletal muscle bundles. It is a rare lipomatous tumor with a predilection for the anterior abdominal wall.[16,17] Lipomas of the forehead are frequently deep-seated, presenting in a submuscular or subgaleal location. They show a predilection for male adults.[18,19]

NEOPLASMS OF SUBCUTANEOUS FAT AT A GLANCE

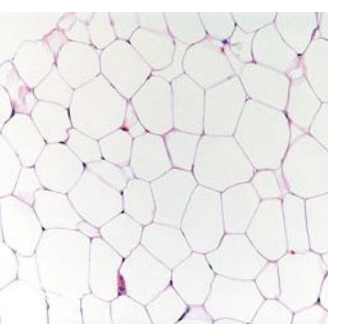


- Adipocytic tumors are the most frequently encountered group of mesenchymal neoplasms. This is due to the high prevalence of lipoma and angiolipoma.
- Tumors range from entirely benign neoplasms (e.g., lipomas) to those of intermediate malignant potential with risk for local recurrence (e.g., atypical lipomatous tumor) to high-grade pleomorphic sarcomas (e.g., pleomorphic liposarcoma).
- Although liposarcoma is the single most frequently encountered sarcoma, the large majority of adipocytic tumors are benign.
- The clinical presentation of adipocytic tumors is generally non-specific.
- Most adipocytic tumors show distinctive cytogenetic abnormalities that may be of diagnostic value.
- Treatment is surgical excision. Adjuvant radiation therapy and/or chemotherapy may be of benefit for treatment of malignant tumors that are not amenable to complete excision or in cases of advanced disease.

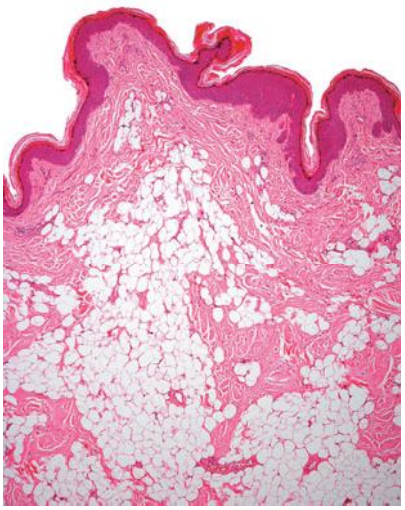
▲ **FIGURE 129-1** Familial multiple lipomatosis. Multiple lipomas of variable size show a symmetric distribution involving the forearms of this middle-aged man.

Histologic Features

Conventional lipomas are circumscribed masses surrounded by a thin fibrous capsule. They are composed of lobules of mature white adipose tissue divided by delicate and inconspicuous fibrous septa containing thin-walled capillary sized vessels (Fig. 129-2). The adipocytes are univacuolated and mature with eccentrically placed, compressed nuclei.

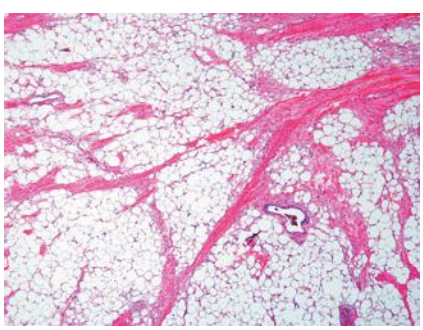


▲ **FIGURE 129-2** Lipoma. Mature univacuolated adipocytes show only mild variation in size, and cytologic atypia is not a feature. Delicate intervening capillaries are present.

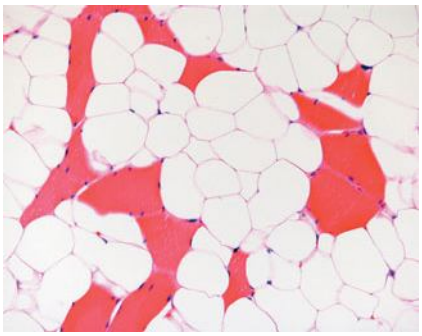


▲ **FIGURE 129-3** Intradermal lipoma. Mature adipocytes diffusely infiltrate pre-existing dermal collagen bundles. Note the sparing of the papillary dermis.

There is only slight variation in adipocyte size, and nuclear atypia is not a feature. Morphologically, lipomas are indistinguishable from the surrounding adipose tissue and the identification of a distinct mass is necessary for the diagnosis. Lipomas may show changes of trauma with varying amounts of fat necrosis and inflammation. Extensive involvement of the dermis is known as *dermal lipoma*. These tumors are not encapsulated and are frequently less circumscribed than other forms of superficial lipoma (Fig. 129-3). Lipomas with increased fibrous tissue are referred to as *fibrolipomas* (Fig. 129-4). In contrast to atypical lipomatous tumors, cellularity is low within the fibrous strands, and no nuclear atypia is present. *Myxolipomas* are characterized by the presence of conspicuous myxoid stroma. *Angiomyxolipoma* or vascular myxolipoma is characterized by a myxoid stromal background in addition to a proliferation of vessels of variable sizes. A lipoma containing



▲ **FIGURE 129-4** Fibrolipoma. This variant is characterized by the presence of increased fibrous tissue within a lipoma.



▲ **FIGURE 129-5** Intramuscular lipoma. Mature adipocytes show an infiltrative growth pattern within skeletal muscle, splaying apart individual muscle fibers. (Used with permission from Dr. J. Hornick, Brigham and Women's Hospital and Harvard Medical School, Boston, MA.)

metaplastic bone or cartilage within the tumor is referred to as an *osteolipoma* or *chondrolipoma*, respectively.

Intramuscular lipoma can either present as a circumscribed intramuscular mass or show an infiltrative growth of adipocytes in between skeletal muscle fibers (Fig. 129-5).

Clinical Course, Prognosis, and Treatment

Lipomas are entirely benign tumors and, with the exception of intramuscular lipomas, local recurrence is rare. The infiltrative variant of intramuscular lipoma is associated with an approximately 19 percent chance of local recurrence, but metastasis does not occur.[16]

LIPOMATOSIS

- Lipomatosis is characterized by diffuse overgrowth of adipose tissue infiltrating through pre-existing structures.
- Different clinical presentations are recognized.

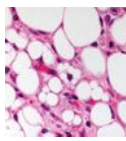
Epidemiology and Clinical Findings

Diffuse lipomatosis[20,21] is characterized by overgrowth of adipose tissue involving subcutaneous tissue and skeletal muscle of the trunk and extremities. Osseous involvement may also be a feature. Young children are predominantly affected, but presentation may become apparent in adulthood. Tumors can grow to a large size, causing disfigurement and loss of function of the affected limb. Due to the diffuse growth of these tumors, complete excision may not be possible and recurrences are frequent.

▲ **FIGURE 129-6** Symmetric lipomatosis. There is diffuse and symmetric overgrowth of adipose tissue affecting predominantly the upper trunk, neck, and proximal arms.

Benign symmetric lipomatosis (Madelung disease, multiple symmetric lipomatosis)[22–29] is characterized by multiple symmetric masses composed of nonencapsulated adipose tissue with a predilection for the subcutaneous tissue and skeletal muscle of the neck, shoulder, and proximal upper limbs (Fig. 129-6). Presentation is in adulthood with a marked male predominance of 15:1. The estimated overall incidence is 1 in 25,000, with increased frequency in the Mediterranean region. The disease is associated with increased alcohol intake in the majority of cases. Two clinical variants are currently recognized. Type 1 disease is characterized by a symmetric distribution of adipose tissue, giving rise to a "pseudoathletic" appearance, whereas type 2 disease shows a more diffuse distribution, giving rise to a picture of more generalized obesity. An associated polyneuropathy affecting sensory, motor, and autonomic function is frequently present. The disease course is slowly progressive, and treatment is difficult due to infiltration of deep-seated structures and major nerves and vessels. There is significant disease-related mortality due to compression of vital structures as well as autonomic neuropathy with sudden cardiac death. Etiologically, the disease has been speculated to be a result of hypertrophy of brown fat due to a defect in adrenergic lipolysis.

Pelvic lipomatosis[30–33] is an unusual proliferation of adipose tissue involving the pelvis and retroperitoneal space. The disorder is most common among men in the third and fourth decades, and blacks account for about two-thirds of cases. Urinary symptoms are frequent presenting signs, and the disease is associated with cystitis in 75 percent of cases. Ob-



structive uropathy and renal failure may be complications of the disease.

Adiposis dolorosa (Dercum disease)[34–41] is rare and typically affects middle-aged women, although men may occasionally also be affected. The disease is typically sporadic, and familial cases are exceptional. There is an increased incidence with obesity. Patients present with multiple painful subcutaneous lipomatous lesions frequently associated with other symptoms such as weakness, depression, confusion, lethargy, or dementia. The disease predominantly involves the arms and trunk but may be progressive to involve large parts of the body. Treatment modalities include pain relief as well as surgical control with excision or liposuction. Weight reduction can be beneficial.

Human immunodeficiency virus lipodystrophy[42–46] occurs in the setting of protease inhibitor treatment or other forms of antiretroviral therapy in patients with acquired immunodeficiency syndrome (see Chap. 198). There is a predilection for cervical fat pads, the breast, and visceral fat. Other associations include hyperlipidemia, insulin resistance, type 2 diabetes, and fat wasting affecting the face and limbs.

Histologic Features

The histologic features of all forms of lipomatosis are similar and show unencapsulated adipose tissue diffusely infiltrating pre-existing structures such as skeletal muscle.

LIPOMATOSIS OF NERVE (FIBROLIPOMATOUS HAMARTOMA OF NERVE)

- Lipomatosis of nerve is a rare tumor that affects infants and children and presents as a growing mass with a predilection for the hand.
- Pathology shows a proliferation of adipose and fibrous tissue within the epineurium and perineurium. The median nerve is predominantly affected.

Epidemiology

Lipomatosis of nerve is rare and affects predominantly infants and young children. Presentation at birth is not uncommon.[47] It is only rarely seen in young adults.

Clinical Findings

Clinical presentation is as a slowly growing mass that may be associated with pain and paresthesia due to compression of the affected nerve. There is a strong predilection for the hand, including the wrist, palm, and fingers, and, less frequently, the foot. The median nerve and its branches followed by the ulnar nerve are most commonly affected.[47] Involvement of cranial nerves and the brachial plexus has been reported but is exceptional.[48,49] In a subset of patients there may be accompanying overgrowth of bone resulting in macrodactyly.

Histologic Features

The lesions are characterized by a proliferation of adipose and fibrous tissue within the epineurium infiltrating along and in between nerve bundles. There is marked concentric fibrosis affecting both epineurium and perineurium.[47] Metaplastic bone formation may rarely occur.[50]

Clinical Course, Prognosis, and Treatment

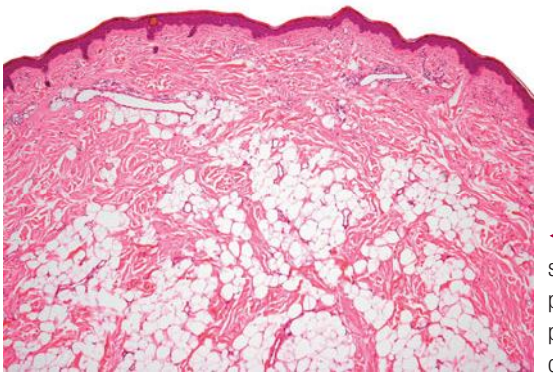
The clinical behavior is entirely benign, but adequate treatment is difficult because of the anatomic location and involvement of major nerves.[47]

NEVUS LIPOMATOSUS SUPERFICIALIS

- Nevus lipomatosus superficialis is a rare entity that affects children and young adults.
- Papules and plaques show a predilection for the buttocks, lumbar back, and posterior thighs.
- Bands of mature adipose tissue infiltrate dermal collagen.

Epidemiology

Nevus lipomatosus superficialis is a rare form of connective tissue–type nevus that affects children and young adults in the first two decades of life. There is an equal gender distribution.[51–55]



◀ **FIGURE 129-7** Nevus lipomatosus superficialis. Infiltration of adipose tissue into the dermis with penetration of dermal collagen is a characteristic finding.

Clinical Findings

The classic presentation is as multiple papules and nodules that may coalesce to form larger plaques. There is a predilection for the buttocks, upper posterior thighs, and lumbar back. Occasionally, involvement may be extensive, and the lesions may form confluent linear plaques along the skinfolds. This phenomenon has been reported as the "Michelin tire man" appearance.[56,57] Solitary lesions occur predominantly in adults and are more likely to represent a fibroepithelial polyp containing adipose tissue.

Histologic Features

The histologic features show mature adipose tissue in varying amounts within the superficial dermis (Fig. 129-7).

ANGIOLIPOMA

- Angiolipoma is a relatively common lesion that presents as a small nodule with a predilection for the forearm.
- Young adults are affected, and lesions are frequently multiple and painful.
- Histologically, this circumscribed lesion shows an admixture of mature adipose tissue and a proliferation of capillary-sized vessels.

Epidemiology

Subcutaneous angiolipomas are relatively frequent and typically occur in young adults in their teens and 20s, with a strong male predilection.[58–60] They are rare in children and in the elderly.

Etiology and Pathogenesis

Angiolipomas have traditionally been classified as adipocytic tumors. In con-

trast to most lipomas, however, they appear to have a consistently normal karyotype, and it has been suggested that they may be reactive or hamartomatous rather than neoplastic.[60] The fact that angiolipomas can occasionally be almost exclusively composed of blood vessels (cellular angiolipoma) has led to the speculation that they may in fact be hemangiomas rather than lipomas.[60] There is an increased familial incidence, but no inheritance pattern has been elucidated as yet.[61]

Clinical Findings

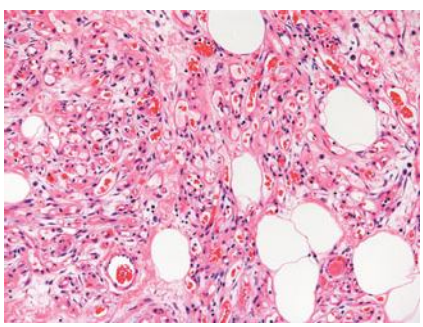
A wide range of sites can be affected, but there is a predilection for the forearm followed by the trunk, upper arm, and legs.[58–60] Angiolipomas are often multiple and present as subcutaneous nodules characteristically smaller than 2 cm. Tenderness and pain are frequently associated symptoms.

Histologic Features

Angiolipomas are circumscribed and encapsulated. They show an admixture of mature fat and capillary-sized small branching vessels in varying proportions (Fig. 129-8; see eFig. 129-8.1 in on-line edition). The vascular density is often increased at the periphery in a subcapsular distribution. Fibrin thrombi are typically encountered. The term *cellular angiolipoma* is applied to those lesions that are almost exclusively composed of vascular elements (see eFig. 129-8.2 in on-line edition).[62–64]

Differential Diagnosis

The appearances of angiolipoma are quite characteristic. The differential diagnosis of cellular angiolipoma includes vascular tumors such as Kaposi sarcoma, spindle cell hemangioma, and angiosarcoma.



▲ **FIGURE 129-8** Angiolipoma. A proliferation of capillary-sized vessels is admixed with mature adipose tissue.

Clinical Course, Prognosis, and Treatment

The clinical behavior of angiolipomas is entirely benign. The tumors are frequently multiple as well as painful, however, and clinical management can be a challenge.

SPINDLE CELL LIPOMA AND PLEOMORPHIC LIPOMA

- Spindle cell lipoma and pleomorphic lipoma are currently considered to represent a morphologic continuum.
- They typically occur on the posterior neck, upper back, and shoulder of middle-aged men.
- Morphologically characteristic is the admixture of mature fat with bland and uniform spindle cells in a myxoid stroma containing ropey collagen bundles and mast cells. Multinucleate (floret-type) giant cells are present in pleomorphic lipoma.

Epidemiology

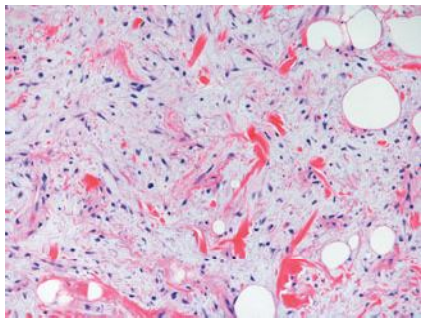
Spindle cell lipoma and pleomorphic lipoma are believed to constitute a morphologic continuum. This view is based on the finding that there is significant clinical, histologic, and cytogenetic overlap and the fact that features of both can be present in a single lesion.[65–73] These lipomas are rare; they represent only approximately 1.5 percent of all fatty tumors and are 60 times less frequent than conventional lipomas.[66] They show a predilection for middle-aged to elderly adults (median age, 55 years) and a strong male predominance.[65–73]

Clinical Findings

Spindle cell and pleomorphic lipoma present as circumscribed, mobile masses, often with a long-standing history. They are small, measuring around 5 cm, and almost exclusively present on the posterior neck, shoulder, and upper back.[65–73] Other anatomic sites in the head and neck region can occasionally be affected. Rarely, these tumors are multiple and familial.[78,79]

Histologic Features

Both tumors are circumscribed and are typically located within the subcutis.



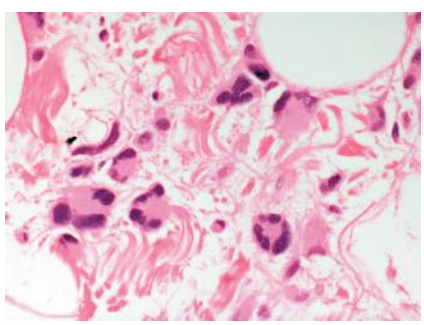
▲ **FIGURE 129-9** Myxoid spindle cell lipoma. Extensive myxoid stromal change is seen in this tumor.

Spindle cell lipoma is characterized histologically by the presence of mature adipocytes admixed with bland-appearing and uniform, stubby spindle cells in a collagenous and myxoid stroma containing ropey collagen fibers and conspicuous mast cells (see eFigs. 129-8.3, 129-8.4, and 129-8.5 in on-line edition). Myxoid change can be prominent (Fig. 129-9), and occasionally slit-like spaces resembling vascular channels may be present (pseudoangiomatous variant).[80] Mitotic activity is virtually absent. The characteristic feature of pleomorphic lipoma is the presence of bizarre multinucleate giant cells, termed *floret cells*. These cells show eosinophilic cytoplasm and multiple crowded and overlapping hyperchromatic nuclei arranged in a circle or semicircle resembling the petals of a flower (Fig. 129-10).

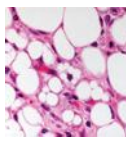
Differential Diagnosis

The differential diagnosis for spindle cell and pleomorphic lipomas includes the following:

- Atypical lipomatous tumor
- Solitary fibrous tumor
- Cellular angiofibroma



▲ **FIGURE 129-10** Pleomorphic lipoma. The characteristic floret-type giant cells contain overlapping hyperchromatic nuclei in a circular or semicircular arrangement. (Used with permission from Dr. S. Banerjee, Christie Hospital, Manchester, UK.)

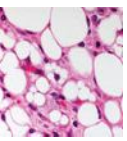


Clinical Course, Prognosis, and Treatment

Spindle cell and pleomorphic lipomas are entirely benign adipocytic neoplasms and local recurrences are rare.

CHONDROID LIPOMA

- Chondroid lipoma is a rare and benign tumor that affects adults and shows a female predominance.
- The anatomic distribution is wide, but there is a predilection for the proximal extremities and limb girdle.
- The unique histologic features include the presence of mature adipose tissue, lipoblasts, and a chondroid matrix.



Epidemiology

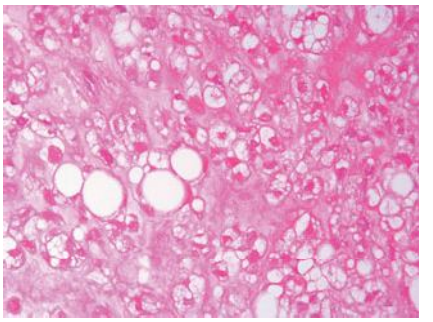
Chondroid lipoma is a relatively recently recognized and exceedingly rare benign lipomatous tumor.[82] It shows a predilection for adults and a wide age distribution with a median of 36 years. There appears to be a significant female predominance (estimated at 1:4).[82]

Clinical Findings

Chondroid lipoma is a relatively small tumor measuring approximately 5 cm. Larger examples of over 10 cm have also been reported. It presents as a painless circumscribed mass of variable duration and often comes to clinical attention because of a history of recent growth. The proximal extremities and limb girdles are the most frequently affected anatomic sites,[82] but the trunk as well as the head and neck region, including intraoral sites, may also be affected.[82,86–88] Tumors are typically deep-seated, involving deep subcutaneous tissue, fascia and skeletal muscle.[82] Imaging studies are rather non-specific and show a multilobular and circumscribed mass containing fatty elements.[88–90]

Histologic Features

The characteristic feature of chondroid lipoma is the admixture of a mature adipocytic component and a chondroid matrix containing lipoblasts.[82] This well-circumscribed tumor is frequently encapsulated and multi-lobulated. It is composed of univacuolated and multivacuolated cells, occasionally with eosinophilic cytoplasm, showing cytologic features reminiscent of those of lipoblasts or



▲ **FIGURE 129-11** Chondroid lipoma. Univacuolated and multivacuolated cells reminiscent of lipoblasts or chondroblasts are present adjacent to mature adipocytes. (Used with permission from Dr. S. Banerjee, Christie Hospital, Manchester, UK.)

chondroblasts (Fig. 129-11).[82] These cells contain small lipid droplets as well as periodic acid-Schiff–positive glycogen.[82] They are arranged in cords, nests, and strands as well as more solid areas set in a background of a chondroid matrix typically containing chondroitin sulfates (see eFig. 129-11.1 in on-line edition).[91] Intricately admixed are variable amounts of mature adipose tissue. Tumors can be highly vascularized and show areas of hemorrhage, fibrosis, and calcifications.

Differential Diagnosis

Differential diagnosis for chondroid lipoma includes the following:

- Myxoid liposarcoma
- Extraskeletal myxoid chondrosarcoma

Clinical Course, Prognosis, and Treatment

Chondroid lipoma is a benign lipomatous neoplasm, and neither recurrences nor metastases have been demonstrated so far. Excision is the treatment of choice.

MYOLIPOMA OF SOFT TISSUE

Epidemiology

Myolipoma of soft tissue is also known as *extrauterine lipoleiomyoma* and is characterized by its admixture of mature adipocytic and smooth muscular components. It is an exceedingly rare tumor occurring in adulthood, with a female predominance of 2:1.[92]

Clinical Findings

Myolipomas can grow to a significant size and average 15 cm. They occur in deep soft tissue of the retroperitoneum, abdominal cavity, and inguinal area but can also arise within subcutaneous tissue of the trunk and extremities. Involvement of deep structures such as skeletal muscle and fascia is frequent. Myolipomas present as palpable masses but may be incidental findings when located at visceral sites.

Differential Diagnosis

The differential diagnosis for myolipoma of soft tissue includes the following:

- Liposarcoma
- Angiomyolipoma

Clinical Course, Prognosis, and Treatment

Myolipoma of soft tissue is a benign neoplasm, and recurrences have not been reported. Complete excision is curative.

HIBERNOMA

- Hibernoma is a benign neoplasm that resembles brown fat and typically presents in adulthood.
- A wide range of anatomic locations may be affected.

Epidemiology

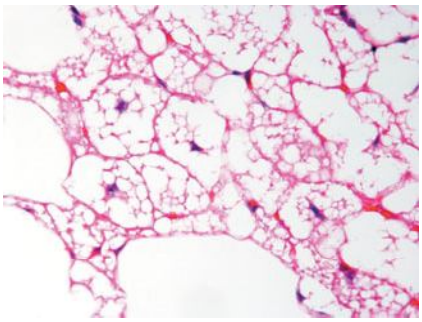
Hibernoma is a well-recognized but rare benign adipocytic tumor that shows a wide age distribution. Young adults (mean age, 38 years) are predominantly affected, but presentation in the pediatric population as well as in the elderly is possible. Males appear to be affected only slightly more frequently than females.[93]

Etiology and Pathogenesis

The etiology of this rare tumor is unclear. Karyotypes can be slightly more complex than those observed in other benign lipomatous tumors, but structural rearrangements involving chromosome band 11q13 appear to be reproducible.[94–97]

Clinical Findings

Hibernoma is a painless, slowly enlarging tumor affecting a wide range of anatomic sites. There appears to be a predilection for areas in which brown fat can be found physiologically, and presentation on the trunk, especially the scapular area, the shoulder, and the head and neck is common. Curiously, however, the thigh appears to be the single most fre-



▲ **FIGURE 129-12** Hibernoma. The characteristic feature is the presence of multivacuolated adipocytes with centrally placed nuclei and clear to eosinophilic granular cytoplasm.

quently affected site.[93] Hibernomas are typically located in subcutaneous tissue or skeletal muscle but may occasionally affect the abdominal cavity, retroperitoneum, or intrathoracic location.[98]

Histologic Features

Hibernoma is a well-demarcated and lobulated neoplasm. The hallmark feature is its morphologic resemblance to brown fat. The tumors are composed of variable numbers of multivacuolated adipocytes with small, centrally placed nuclei and pale to eosinophilic and granular cytoplasm (Fig. 129-12). Based on the appearance of these brown fat cells, the quality of intervening stroma, and the presence of a spindle cell component, six histologic variants are recognized.[93]

The typical variant is the most frequently encountered form and is characterized by large numbers of brown fat cells admixed with mature white fat (see eFig. 129-12.1 in on-line edition). Those tumors composed almost exclusively of brown fat cells with palely staining cytoplasm are further subclassified as the *pale cell subtype*. Tumors are labeled *eosinophilic subtype* when at least 50 percent of brown fat cells contain a deeply eosinophilic and granular cytoplasm. The *mixed subtype* is intermediate between the two and shows a roughly equal distribution of eosinophilic and pale-staining brown fat cells. Myxoid, lipoma-like, and spindle cell variants exist.

Differential Diagnosis

The differential diagnosis of hibernoma includes the following:

- Granular cell tumor
- Spindle cell lipoma
- Atypical lipomatous tumor/well-differentiated liposarcoma

Clinical Course, Prognosis, and Treatment

- The behavior of hibernoma is entirely benign without recurrence after local excision.

LIPOBLASTOMA/ LIPOBLASTOMATOSIS

- Morphologically, the benign adipocytic neoplasm lipoblastoma resembles fetal adipose tissue. It is most frequently found in individuals younger than 5 years of age.
- Lipoblastoma has a multilobular and circumscribed appearance, whereas lipoblastomatosis shows an infiltrative growth.

Epidemiology

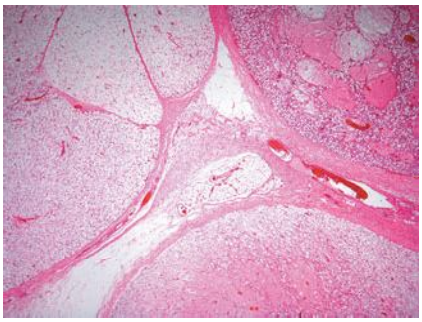
Lipoblastoma/lipoblastomatosis is an uncommon neoplasm affecting infants and young children. Its incidence decreases significantly in those older than 5 years of age, and presentation in adolescents is rare.[104–109] Infrequently, tumors may be congenital.[110–112] There is a male predominance, with a male-female ratio of approximately 2:1.[104–109]

Clinical Findings

Most tumors present as painless, slowly growing, solitary soft-tissue masses. Lipoblastomas are well circumscribed and located in subcutaneous tissue. In contrast, tumors with an infiltrative growth often extend into deeper structures such as skeletal muscle and are termed *lipoblastomatosis*.[109] The extremities, trunk, and head and neck are predominantly affected sites. Visceral involvement of retroperitoneum, mediastinum, peritoneal cavity, or solid organs is rarely seen.[104–109] Tumors are relatively small, measuring around 5 cm. However, larger tumors of more than 20 cm have been reported. In certain locations, tumors can become symptomatic due to compression of adjacent structures and organs.

Histologic Features

Lipoblastomas are well-circumscribed, lobulated tumors with fibrous septa (Fig. 129-13) composed of an admixture of mature and immature adipocytes in varying proportions (see eFig. 129-13.1 in on-line edition). Lipoblasts are present in different stages of development ranging from univacuolated forms



▲ **FIGURE 129-13** Lipoblastoma/lipoblastomatosis. Lipoblastoma is a circumscribed tumor showing prominent multilobulation with dividing fibrous septa. (Used with permission from Dr. S. Banerjee, Christie Hospital, Manchester, UK.)

with eccentrically placed and compressed nuclei to bivacuolated and multivacuolated forms (see eFigs. 129-13.2 and 129-13.3 in on-line edition).

Differential Diagnosis

The differential diagnosis of lipoblastoma/lipoblastomatosis includes the following:

- Myxoid liposarcoma
- Atypical lipomatous tumor
- Hibernoma
- Lipofibromatosis

Clinical Course, Prognosis, and Treatment

Lipoblastoma/lipoblastomatosis is a benign tumor with a tendency to recurrence if inadequately excised. Complete surgical excision is curative and is the treatment of choice.

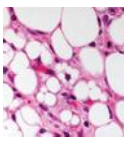
HEMOSIDEROTIC FIBROHISTIOCYTIC LIPOMATOUS LESION/TUMOR

Epidemiology

The exceedingly rare hemosiderotic fibrohistiocytic lipomatous lesion or tumor was first described by Marshall-Taylor and Fanburg-Smith[120] in 2000. Only 25 cases have been reported in the literature so far.[120–122] Although the age range of occurrence is wide, the lesion typically presents in adulthood (median age, 50 years) and affects women more frequently than men.[120,121]

LIPOFIBROMATOSIS

Lipofibromatosis is an uncommon pediatric neoplasm that predominantly af-



fects infants at a median age of 1 year.[124–127] It can be congenital, but children and adolescents may also be affected. There appears to be a significant male predominance.

ATYPICAL LIPOMATOUS TUMOR/WELL-DIFFERENTIATED LIPOSARCOMA

Epidemiology

Atypical lipomatous tumor/well-differentiated liposarcoma is a neoplasm of adulthood with a peak incidence in the sixth decade.[128–136] It represents the largest subgroup of liposarcomas. There is no gender predilection.

Clinical Findings

Tumors typically present in deep soft tissue. The subcutaneous tissue may occasionally also be involved. The predominantly affected site is the musculature of extremities with a predilection for the thigh, followed by the retroperitoneum, groin, and paratesticular area as well as the mediastinum.[128–136] A wide range of other anatomic sites including the larynx, orbit, oral cavity, and vulva may be affected.[144–147] An enlarging painless mass is the typical presenting sign, and especially in a retroperitoneal location, tumors can grow to a very large size before becoming symptomatic.

Histologic Features

Atypical lipomatous tumors are large, multilobulated, and most often circumscribed. The most frequently observed adipocytic (lipoma-like) morphologic variant closely resembles a lipoma. It is composed of relatively mature-appearing adipocytes with marked variation in cell size (see eFig. 129-13.4 in on-line edition). Additional findings include focal adipocytic atypia (see eFig. 129-13.5 in on-line edition) and the presence of hyperchromatic and often multinucleate bizarre stromal cells in cellular fibrous septa (see eFigs. 129-13.6 and 129-13.7 in on-line edition). Floret-type giant cells may also be a feature (see eFig. 129-13.8 in on-line edition). Lipoblasts may be monovacuolated or multivacuolated and vary in number (see eFig. 129-13.9 in on-line edition). They may be entirely absent and are not a prerequisite for the diagnosis. Sclerosing, inflammatory, and spindle cell variants exist.

Differential Diagnosis

The differential diagnosis of atypical lipomatous tumor/well-differentiated liposarcoma includes the following:

- Lipoma
- Spindle cell/pleomorphic lipoma
- Dedifferentiated liposarcoma
- Angiomyolipoma
- Massive localized lymphedema

Clinical Course, Prognosis, and Treatment

The clinical behavior and prognosis are largely dependent on the anatomic site. Surgery is curative at anatomic locations where complete surgical excision with clear margins can be achieved (e.g., somatic soft tissue such as the limbs). The estimated rate of progressing to dedifferentiated liposarcoma is less than 2 percent with a mortality rate of virtually zero at these anatomic locations. In contrast, tumors arising at deep locations such as the retroperitoneum, mediastinum, or spermatic cord, where complete surgical clearance is not possible, are characterized by repeated local recurrence and ultimately may result in death from uncontrolled local disease or dedifferentiation with metastasis. The overall risk of development of dedifferentiated liposarcoma is estimated to be higher than 20 percent with an overall mortality rate of around 80 percent for tumors occurring in the retroperitoneum. The disease has a protracted course, and the median survival time ranges from 6 to 11 years.[132,135,150] The primary approach to treatment is surgical excision. Adjunct chemotherapy and radiation treatment are reserved for advanced disease.

DEDIFFERENTIATED LIPOSARCOMA

- Tumors typically present as large masses in the retroperitoneum of adults.
- The disease course is protracted, with a high rate of local recurrence and a significant risk for metastasis and associated mortality.
- The morphologic characteristic is the presence of non-lipogenic areas adjacent to well-differentiated liposarcoma.

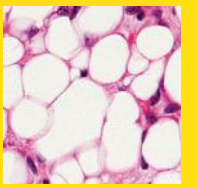
Epidemiology

The epidemiologic features of dedifferentiated liposarcoma are similar to those of well-differentiated liposarcoma, and it typically affects adults in the sixth decade.[151–153] There is no gender predilection. De novo presentation is most commonly seen, occurring in approximately 90 percent of cases. Only around 10 percent of cases represent dedifferentiation of a previously well-differentiated liposarcoma.[151,152]

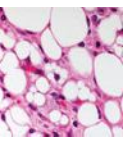
Clinical Findings

Tumors present as large painless masses with a predilection for the retroperitoneum followed by the limbs and paratesticular area and spermatic cord.[151–153]

ATYPICAL LIPOMATOUS TUMOR/WELL-DIFFERENTIATED LIPOSARCOMA AT A GLANCE



- Atypical lipomatous tumor/well-differentiated liposarcoma is a tumor of adulthood that presents as an enlarging mass with a predilection for the extremities, retroperitoneum, and paratesticular tissue.
- The most important prognostic predictor is anatomic location:
  - The rate of recurrence, risk of dedifferentiation, and associated mortality is negligible at sites amenable to surgical excision (i.e., extremities).
  - In contrast, tumors at anatomic sites such as the retroperitoneum and paratesticular region, where complete excision with tumor-free margins cannot be achieved, show a disease course characterized by multiple recurrences and a high risk of dedifferentiation and metastasis. Long-term mortality is high.
- Tumors at surgically amenable sites for which excision is curative are referred to as *atypical lipomatous tumors*, whereas those tumors arising in the retroperitoneum or other areas where clear margins cannot be achieved should be regarded as *well-differentiated liposarcoma*.



Other sites, including the head, neck, and trunk, are rarely affected. Presentation in the subcutis is unusual.[155]

Histologic Features

The tumors are multilobulated and consist of yellow, fatty areas as well as discrete more solid areas representing dedifferentiation. The characteristic histologic finding is the presence of both atypical lipomatous tumor/well-differentiated liposarcoma and non-lipogenic sarcoma. The proportions may vary, and careful gross examination and adequate sampling may be necessary to identify the lipogenic areas. There is usually a very sharp demarcation between lipogenic and non-lipogenic areas (see eFig. 129-13.13 in on-line edition), but a more gradual transition or co-mingling may also be seen. The non-lipogenic component is most frequently morphologically high grade, showing a pleomorphic sarcoma–like (pleomorphic and storiform malignant fibrous histiocytoma–like) (Figs. 129-14 and 129-15) or a myxofibrosarcoma-like appearance.[151–153,156]

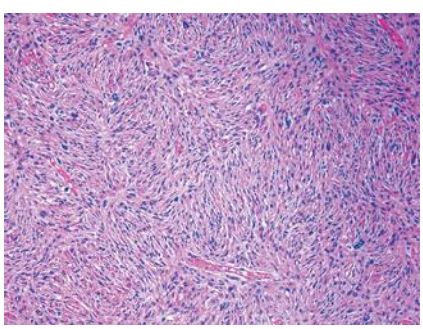
Differential Diagnosis

The differential diagnosis of dedifferentiated liposarcoma includes the following:

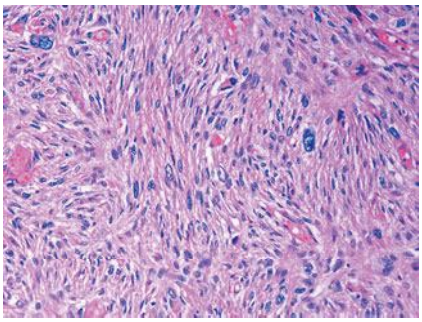
- Spindle cell liposarcoma
- Pleomorphic liposarcoma
- Other pleomorphic sarcomas

Clinical Course, Prognosis, and Treatment

Dedifferentiated liposarcoma is characterized by a protracted course with a high risk of local recurrence. Retroperitoneal tumors almost invariably recur if followed over a long period of time. The overall risk of distant spread is estimated at around 20 percent, with a disease-related



▲ **FIGURE 129-14** Dedifferentiated liposarcoma. Tumor cells are arranged in short fascicles and give rise to a storiform appearance.



▲ **FIGURE 129-15** Dedifferentiated liposarcoma. There is an admixture of spindle cells and large pleomorphic cells.

mortality rate of approximately 30 percent.[152] Although these rates are likely to be higher with long-term follow-up, the prognosis appears to be more favorable than that for other high-grade pleomorphic sarcomas, which are associated with a high mortality rate and shorter time to death. Anatomic location is the most important prognostic factor, and retroperitoneal tumors are associated with a poor prognosis. In contrast, neither the extent of dedifferentiation nor the morphologic features appear to be prognostically predictive. The mainstay of treatment is surgical removal with adjuvant chemotherapy and radiation in advanced disease.

MYXOID/ROUND CELL LIPOSARCOMA

Epidemiology

Myxoid liposarcomas represent approximately 10 percent of all soft-tissue sarcomas. They comprise more than one-third of all liposarcomas and are the second most frequent variant of liposarcoma.[159] The tumor presents in young to middle-aged adults with a peak in the fourth to fifth decade and a slight male predominance.[159–161]

Clinical Findings

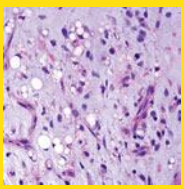
Presentation as a large, painless mass with a predilection for the extremities is characteristic. Tumors are located in deep soft tissue and involve the thigh in over two-thirds of cases.[159–161] Presentation in subcutis or retroperitoneum is rare. Not infrequently, patients are found to have multifocal disease at initial presentation, which is generally regarded to represent metastases.[169]

Histologic Features

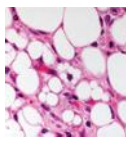
Tumors are large, well circumscribed, and multinodular with a gelatinous cut surface on gross examination. The appearance becomes fleshier in areas with increased cellularity, but large areas of tumor necrosis are not typically seen.

Microscopically, myxoid liposarcoma is a lobulated tumor composed of a mixture of bland-appearing oval mesenchymal cells without evidence of adipocytic differentiation and small univacuolated or bivacuolated lipoblasts, often with a signet-ring cell appearance (see eFigs. 129-15.1 and 129-15.2 in on-line edition). The cellularity is low but increased toward the periphery of the tumor lobules (see eFig. 129-15.1 in on-line edition). The cells are placed in a myxoid matrix showing a characteristic pattern of delicate, branching capillary-sized vessels often referred to as *chicken wire* or *crow's feet* (see eFig. 129-15.3 in on-line edition). In the central areas the extracellular mucin may become confluent to form mucin pools, giving rise to a pulmonary edema–like appearance (see eFig. 129-15.4 in on-line edition). In the well-differentiated areas, the tumors lack significant cytologic atypia, mitotic activity, or tumor necrosis. Poorly differentiated, high-grade tumors are characterized by increased cellularity with the formation of solid sheets of small to medium-sized round cells showing scant acidophilic cyto-

MYXOID/ROUND CELL LIPOSARCOMA AT A GLANCE



- Presentation is as a large mass involving the extremities and in particular the thigh of middle-aged adults.
- There is a significant rate of local recurrence as well as metastasis.
- Tumors are lobulated and circumscribed and are composed of a myxoid matrix containing primitive mesenchymal cells and lipoblasts in varying stages of differentiation. A prominent vascular pattern is a characteristic feature.
- Round cell liposarcoma is currently regarded to represent the high-grade end of the morphologic spectrum.



plasm (see eFig. 129-15.5 in on-line edition). Mitotic figures are more easily identified, but nuclear pleomorphism is not a feature.

Differential Diagnosis

The differential diagnosis of myxoid liposarcoma includes the following:

- Lipoblastoma
- Myxofibrosarcoma
- Low-grade fibromyxoid sarcoma
- Chondroid lipoma
- Myxoid melanoma

Clinical Course, Prognosis, and Treatment

The clinical course of myxoid liposarcoma is characterized by local recurrence with a rate of distant metastasis of 30 percent to 40 percent.[159–161] There is an unusually high incidence of soft-tissue and bone metastases in addition to metastases to the lung. Patients with multifocal disease at presentation have a poor prognosis, and adverse histologic features include the presence of round cell differentiation in more than 5 percent of the tumor, tumor necrosis, and p53 overexpression.[160,161,170]

PLEOMORPHIC LIPOSARCOMA

- Pleomorphic liposarcoma is an aggressive sarcoma that shows a predilection for the extremities of adults and is associated with a high rate of metastasis and mortality.
- Histologic examination shows a pleomorphic high-grade sarcoma containing variable numbers of lipoblasts.

Epidemiology

Pleomorphic liposarcoma is a rare tumor representing only approximately 5 percent of all liposarcomas and up to 20 percent of pleomorphic sarcomas.[171,172] It shows a slight male predominance and presents in adulthood (median age, 50 to 60 years). The age range, however, is wide.[173–175]

Clinical Findings

Tumors present as enlarging firm masses, frequently with a short history. They are typically large, deep-seated, and subfascial sarcomas measuring 8 to 10 cm in median. Presentation in subcutaneous tissue is less frequent, and dermal location is unusual.[173–176] The extremities are the most frequently affected sites, and there is a predilection for the lower limbs. The trunk, retroperitoneum, head and neck, abdomen, and pelvis may also be involved.

Histologic Features

Tumors can be well circumscribed but unencapsulated. More frequently, however, they have infiltrative margins. In its classic appearance pleomorphic liposarcoma shows features of a high-grade pleomorphic (malignant fibrous histiocytoma–like) sarcoma containing pleomorphic spindle cells and multinucleate giant cells (see eFig. 129-15.6 in on-line edition). Admixed are lipoblasts in varying numbers. They may be scarce in areas or arranged in larger sheets (see eFig. 129-15.7 in on-line edition). Mitotic figures are frequent, including atypical forms, and areas of necrosis are often present. An additional finding is the presence of intracellular as well as extracellular eosinophilic hyaline droplets.

Two morphologic variants, a high-grade myxofibrosarcoma-like and an epithelioid variant, are recognized.

Differential Diagnosis

The differential diagnosis of pleomorphic liposarcoma includes the following:

- Dedifferentiated liposarcoma
- Leiomyosarcoma
- Pleomorphic rhabdomyosarcoma
- Myxofibrosarcoma
- Melanoma
- Carcinoma

Clinical Course, Prognosis, and Treatment

Pleomorphic liposarcoma is characterized by a relatively aggressive clinical course with a more than 30 percent rate of local recurrence, a 30 percent to 50 percent metastatic rate, and an estimated overall 5-year survival rate of 50 percent to 60 percent. The lung is the preferred metastatic site. The treatment is surgical with adjuvant radiation and chemotherapy for advanced disease.

SECTION 24

SKIN IN NUTRITIONAL, METABOLIC, AND HERITABLE DISEASE

CHAPTER 130

Cutaneous Changes in Nutritional Disease

Melinda Jen
Kara N. Shah
Albert C. Yan

Nutrition is the complex series of events by which living organisms consume and assimilate foods and other nutrients to live, grow, and maintain homeostasis. Proper nutrition involves the consumption of key macronutrients in balanced tandem with essential micronutrients. Consisting of carbohydrates, proteins, and lipids, macronutrients are those that are needed in large quantities by an organism to both fuel metabolic processes and provide the substrate for building and maintaining cellular structure. By contrast, micronutrients signify vitamins and minerals, which, though required in relatively minute quantities, are essential to good health. Clinical disease results when disturbances occur in that equilibrium—most commonly from nutrient deficiencies, but also from an unbalanced ratio of consumed nutrients, or, less commonly, from nutrient excesses.

With an improved understanding of the role of diet in health and the advent of nutritional supplements, longstanding scourges such as scurvy, beriberi, and pellagra have largely become diseases of historical interest. Even so, nutritional diseases remain problematic in developing countries and in settings of war, famine, and poverty. In industrialized countries, nutritional diseases may still arise among the disenfranchised: the homeless and those suffering from alcoholism or other forms of substance abuse. Individuals at risk also include those with derangements in their normal diets such as might be encountered with eating disorders, unusual dietary habits, or with parenteral nutrition. Hypercatabolic states, exemplified by cancer, acquired immunodeficiency syndrome, hepatic or renal disease, and certain disease states such as carcinoid syndrome, may develop nutrient deficiencies even in the face of normal intake due to increased metabolic requirements. Excessive nutrient losses may occur from decreased absorption arising from gastrointestinal diseases such as cystic fibrosis, inflammatory bowel disease, celiac disease, or after gastrointestinal surgery. Those receiving chronic medications, such as anticonvulsants or antibiotics, may experience impaired utilization of their nutrients when their medications interfere with gastrointestinal absorption and normal metabolism. Underlying genetic metabolic defects, enzyme deficiencies, hepatic disease, or drug-nutrient interactions may also impair utilization of nutrients. By contrast, syndromes of nutrient excess generally stem from dietary surplus or iatrogenic therapeutic intake.

Patients at risk for one nutrient deficiency may be suffering from other concomitant deficiencies as well. Appropriate evaluation of the patient with suspected nutritional disease should commence with a detailed history of dietary and medication intake, a review of past medical and family history, and a complete physical examination with careful inspection of the skin, with special attention paid to the status of hair, nails, and mucous membranes. Although some skin findings may be pathognomonic for certain nutritional disorders, individual physical findings are more oftentimes non-diagnostic. Clinical improvement after replacement therapy may represent the best or only means to confirm the clinical diagnosis of some nutritional deficiencies. This chapter reviews the important clinical features observed in nutritional disease states.

◀ Scleroderma: CREST syndrome. Numerous macular or matlike telangiectases without other findings of scleroderma on the face. Complete features include calcinosis cutis, Raynaud phenomenon, esophageal dysmotility, sclerosis, and telangiectasia.

MACRONUTRIENTS

Protein-Energy Malnutrition

EPIDEMIOLOGY Protein-energy malnutrition (PEM) is a medical concern of global significance. The United Nations estimates that 852 million individuals, including approximately 170 million or a quarter of the world's children, suffer from PEM,[1] and up to 5 million deaths each year can be attributed to PEM alone.[2]

In developing countries, malnutrition most commonly arises as a result of inadequate dietary intake, often compounded by disease. War, famine, and poverty states often aggravate the inadequate access to food, which may arise from political unrest, natural disasters, infectious diseases, seasonal and climatic factors, insufficient food production, lack of education, poor sanitation, regional and religious practices, and the limited availability of health care.[3] In Western industrialized countries such as the United States, less than 1 percent of children nationally suffer from PEM. When it is encountered, chronic illness, malabsorption, presumed food allergies, nutritional ignorance, and fad diets are more typical etiologies.

ETIOLOGY AND PATHOGENESIS *Protein-energy malnutrition* refers to a spectrum of disorders describing varying degrees of protein and calorie deficiency. Several

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

sub-types of PEM have been defined on the basis of relative deficiencies in protein and total calorie intake.

Children with marasmus suffer from severe wasting and stunting and are at less than 60 percent expected body weight for age. The term *marasmus* derives from the Greek *marasmos* meaning "wasting." These changes are the result of chronic and global nutrient deficiencies, often because of a lack of available food. Children with kwashiorkor have body weights less than 60 percent to 80 percent expected for age, generally arising from a diet of grain-derived foods without adequate accompanying protein or fat. This might occur in geographic areas where grains are more plentiful, but where more expensive proteins and fats are not. In fact, the term *kwashiorkor* derives from the Ghanese term for "the one who is deposed," referring to the child who is weaned off of breast milk onto a carbohydrate-rich but often protein-poor diet when the next sibling is born. The exclusive use of rice beverages, so-called "rice milk" products, as a substitute for baby formulas—either because of their lower cost or because of their perceived hypoallergenicity—has been linked to the development of kwashiorkor among infants in the United States and other western countries.[4–6] A hybrid form of malnutrition in which stunting of growth is associated with edema has been termed *marasmic kwashiorkor*.

The pathophysiology of these disorders can also be conceptualized as adapted and nonadapted forms of starvation. In adapted starvation (marasmus), decreased intake of all macronutrients, particularly carbohydrates, suppresses insulin production. Catabolic hormones thereby act unopposed to stimulate the conversion of glycogen into glucose. In the early stages of adapted starvation, muscle breakdown occurs during the first 24 hours, permitting gluconeogenesis to release glucose into the systemic circulation. Fat breakdown creates ketone bodies that can also be utilized by the brain and central nervous system. This reduces the need for further muscle breakdown and therefore ammonia synthesis so that lean body mass and some protein synthesis can be spared. In prolonged states of adapted starvation, wasting occurs and lean body mass is eventually utilized when all other sources are expended; in the absence of additional nutrient intake, the organism dies. In nonadapted starvation states (kwashiorkor), an imbalance results when intake of carbohydrate is increased relative to decreased intake of protein and fat. Without concomitant fat and protein intake, insulin continues unabated, which suppresses protein production. Hypoproteinemia, edema, and diarrhea develop, and affected individuals are unable to manufacture lipoproteins, so fats accumulate in the liver; more important, necessary immune proteins are not produced, so patients become susceptible to opportunistic infection and septicemia, which represent the major causes of mortality in these patients.

Although the concepts of adapted and nonadapted starvation provide convenient explanations for why some children develop PEM, exactly why some children develop marasmus and others develop kwashiorkor in the face of starvation remains controversial.

CLINICAL FINDINGS Childhood is marked by periods of significant and rapid growth and development, and nutritional deprivation often manifests as alterations in these patterns of normal growth and development. Failure to thrive, a key finding in patients with PEM, may appear first as wasting (poor weight gain or weight loss), and eventually, as decreased rates of linear growth (stunting). Various measurements have been recommended as markers for malnutrition, and include: body weight and length/height relative to age, body mass index, triceps or middle upper arm circumference, as well as skin and hair characteristics.[7,8] Suboptimal neurodevelopmental outcomes, heightened susceptibility to infection, and increased mortality may also be observed in chronically malnourished children.

Marasmus typically affects infants younger than 1 year of age. The physical findings of marasmus include dry, thin, loose, wrinkled skin resulting from loss of subcutaneous fat with an emaciated appearance[9] (Fig. 130-1). Hair growth slows and examination may reveal easy hair loss, leading to thin, fine, brittle, hair and alopecia. Increased lanugo hair may also be present. Nails may show signs of fissuring, with impaired growth.[10] As the body mobilizes all endogenous energy stores to survive, both subcutaneous fat and muscle mass are lost. The loss of buccal fat pads creates the aged or wizened appearance attributed to children with marasmus that has been referred to disparagingly as "monkey facies" (Fig. 130-2). Perianal fat loss can lead to rectal prolapse, and abdominal muscle hypotonia may result in abdominal distention.[11] Constipation may alternate with periods of diarrhea, which may or may not be associated with concomitant gastrointestinal infection. Angular cheilitis and mucous membrane changes have also been observed in patients with marasmus.[12] Patients often show both decreased resting body temperature and bradycardia.

▲ **FIGURE 130-1** Marasmus. General appearance with advanced disease.

The hallmark features of kwashiorkor—also known as *edematous* or "wet" *PEM*—include failure to thrive in association with edema and is primarily noted in children between 6 months and 5 years of age. Children are often initially irritable, but may become lethargic and apathetic. In contrast to marasmus, skin findings are common in kwashiorkor. The generalized dermatitis seen in edematous PEM has been likened to flaking enamel paint, with the pattern of skin fissuring suggesting cracked or

▲ **FIGURE 130-2** Marasmus. "Monkey facies" in an Arab infant, with wrinkled skin and loss of subcutaneous fat.

◀ **FIGURE 130-3** The "flaky paint" or "crazy pavement" dermatitis of kwashiorkor.

"crazy" pavement (Fig. 130-3). Increased pigmentation of skin may be observed on extensor surfaces of the arms and legs. Hair often changes from its natural color, typically developing a red tint (Fig. 130-4A) before further pigment dilution results in light, gray-white hair (see Fig. 130-4B). If a child experiences intermittent periods of kwashiorkor and improved nutrition, alternating bands of light and dark color within the hair shaft may be observed and has been referred to as the "flag sign" (see Fig. 130-4A). Increased lanugo hair can also be noted in kwashiorkor. In addition to the peripheral edema, a direct consequence of hypoproteinemia, distention of the abdomen is noted as a result of fatty infiltration of the liver.

Adults may also be at risk for PEM, particularly those suffering from chronic illnesses, eating disorders such as anorexia nervosa, and the elderly. The prevalence of PEM in adult dialysis patients has been estimated at 25 percent to 50 percent and is posited to occur as a result of semistarvation with inadequate caloric and protein intake, possibly complicated by the presence of a chronic systemic inflammatory response to dialysis.[13] Cases of macronutrient PEM have been reported as a complication of bariatric surgery.[14] The manifestations of PEM in adults may be less prominent, manifesting more as xerosis or acquired ichthyosis and may be the result of decreased sebaceous gland secretions or concurrent micronutrient deficiency.[15]

Hyperpigmentation at characteristic sites may also be present, including the perioral, periocular, and malar areas. Diffuse telogen effluvium; lanugo; and thin, dry, dull hair has also been reported in adult PEM.[16]

LABORATORY TESTING Initial laboratory testing in PEM recommended by the World Health Organization (WHO)[17] includes screening for hypoglycemia, anemia, and an investigation into potential comorbid infectious diseases. Because patients with PEM are at significantly increased risk of serious infection, examination of urinalysis for urinary tract bacterial infection and, in the appropriate geographic areas, blood smear for malaria parasites and feces for blood, ova, and parasites is essential. Skin testing for tuberculosis should be performed. Chest radiography may demonstrate concomitant signs of bacterial pneumonia, tuberculosis, heart failure, rickets, and fractures. Patients with kwashiorkor will also demonstrate hypoproteinemia, which may help guide treatment and prognosis. Evaluation of electrolyte levels before treatment should be interpreted with caution, as refeeding will likely alter mineral balances.

Histologic evaluation is generally unnecessary as the clinical features in association with an appropriate history is diagnostic. Histologic evaluation of the skin, however, reveals increased thickness of the stratum corneum, atrophy of the granular layer, increased basal layer pigmentation, reduction of collagen fibers, and crowding of elastic fibers. Atrophy of the hair appendages with sparing of the sweat gland apparatus can also be noted.[18]

TREATMENT Patients with severe PEM often require hospitalization due to the concurrent risks of hypoglycemia, hypothermia, dehydration, and sepsis. Individuals who are not awake and responsive may require intravenous hyperalimentation during the initial stages of therapy; care must be taken to avoid excessively rapid rehydration due to the risks of congestive heart failure. Oral refeeding using oral rehydration salts containing a mixture of essential electrolytes is generally preferred at least until diarrhea subsides or using fortified formulas as soon as these can be tolerated. Because severely malnourished children are relatively immunocompromised, empiric antibiotic therapy may be considered on admission for suspected sepsis, and any identified infections should be appropriately addressed.[17]

DIFFERENTIAL DIAGNOSIS Differential diagnoses include acrodermatitis enteropathica (AE), atopic dermatitis, seborrheic dermatitis, and Langerhans cell histiocytosis.

Essential Fatty Acids

EPIDEMIOLOGY Naturally occurring essential fatty acid (EFA) deficiency states are uncommon in humans. Cases of deficiency arise instead from inadequate intake, malabsorption, or excessive loss. In the past, prolonged parenteral nutrition was a common cause of EFA deficiency, but, with the introduction of lipid supplementation during parenteral nutrition in 1975, the incidence of EFA deficiency has decreased substantially. Patients at risk for EFA deficiency include those with poor dietary intake, including alcoholics and patients with anorexia nervosa, or those with malabsorptive conditions such as biliary disease, inflammatory bowel disease, and

▲ **FIGURE 130-4** **A.** Flag sign in a Salvadoran child. **B.** Hypomelanization of the hair and skin.

post-gastrointestinal surgery (e.g., bariatric surgery), and may represent one of the primary etiologies for the characteristic rash observed in cystic fibrosis patients.[19] Premature, low-birthweight infants are born with inadequate EFA stores and are at special risk.

ETIOLOGY AND PATHOGENESIS EFAs represent a group of 18-, 20-, or 22-carbon polyunsaturated fatty acids that cannot be synthesized de novo by the human body. The ω-3 series of fatty acids is found in fish oils and is derived from α-linoleic acid. The ω-6 series is found in vegetable oils and is derived from linoleic acid.[9] Linoleic acid and α-linoleic acid are the two EFAs that serve as precursors for other EFAs and therefore must be obtained from dietary intake. In cell membranes, EFAs increase lipoprotein unsaturation to modulate cell membrane fluidity. Arachidonic acid, a derivative of linoleic acid, is converted into prostaglandins, eicosanoids, and leukotrienes, which are important mediators of inflammation. In the epidermis, linoleic acid contributes to lamellar granule formation in the stratum corneum. EFAs, therefore, play a number of key roles in maintaining homeostasis.

CLINICAL FINDINGS Skin manifestations of EFA deficiency include xerosis; scaly, diffuse erythema; and associated intertriginous erosions. Poor wound healing, traumatic purpura secondary to capillary fragility, brittle nails, and alopecia may be observed. Affected individuals may also demonstrate hyperpigmentation or hypopigmentation of the hair. Fatty liver infiltration, increased susceptibility to infection, a blunted immune response, anemia, thrombocytopenia, and growth retardation can also be observed.

LABORATORY TESTING In EFA deficiency states, linoleic acid levels are low, and the enzymes that normally convert linoleic acid to arachidonic acid use oleic acid to create the abnormal byproduct 5,8,11-eicosatrienoic acid. Laboratory evaluation would therefore demonstrate decreased levels of linoleic and arachidonic acids, and elevated plasma levels of 5,8,11-eicosatrienoic acid. Measurements documenting an increased ratio (≥ 0.2) of this abnormal intermediary relative to arachidonic acid is diagnostic for EFA deficiency.

TREATMENT Although topical application of sunflower seed and safflower oils, which contain linoleic acid, may improve the clinical cutaneous findings of EFA deficiency,[20] topical absorption is unpredictable[21] and optimal treatment typically consists of oral or intravenous supplementation of EFA. To prevent EFA deficiency, EFA should represent 1 percent to 2 percent of total daily calories.[22]

MICRONUTRIENTS

Fat-Soluble Vitamins

VITAMIN A (RETINOL) ***Etiology and Pathogenesis.*** Vitamin A is a fat-soluble vitamin involved in retinal photoreceptor function, epithelial proliferation, and keratinization. The two most clinically important metabolites of vitamin A are retinal, which is a key component of rhodopsin generation, and retinoic acid, which regulates cell differentiation.[23] Dietary intake of vitamin A derives from both plant and animal sources. Plant sources include dark, green, leafy vegetables; red palm oil; and brightly colored fruits such as papaya, mango, carrots, tomatoes, apricots, and cantaloupe. In plants, the vitamin A precursor β-carotene can be found as a two-molecule complex of the carotenoid known as *retinal*. Retinal is reduced to retinol in the intestinal villous cells. Animal sources of vitamin A include egg yolk, liver, fish, fortified milk, and other dairy products. In animal sources, vitamin A exists as retinyl esters, which are then hydrolyzed to retinol in the intestinal lumen and then absorbed into intestinal mucosal cells. All retinol vitamin A alcohol is esterified to retinyl esters within the intestinal mucosa, released into the bloodstream bound to chylomicrons, and then transported to the liver for storage. Here, vitamin A can be stored as retinyl esters in the liver; when needed, this storage form may be converted to retinol and transported with retinol-binding protein and transthyretin and circulated throughout the body.

Vitamin A Deficiency. **EPIDEMIOLOGY.** Vitamin A deficiency (VAD) can result in cutaneous as well as ocular complications. It is, in fact, the most common cause of preventable blindness in children, according to the WHO.[24] VAD has also been associated with defects in immune regulation.

ETIOLOGY AND PATHOGENESIS. The primary causes of VAD continue to be inadequate intake, fat malabsorption states, and liver disease. In the United States, inadequate intake can be seen in individuals with eating disorders, restrictive diets, and chronic illness. Because vitamin A is fat-soluble, conditions associated with malabsorption of fat, such as pancreatic or biliary tract disease, celiac disease, Crohn disease, Shwachman-Diamond syndrome, cystic fibrosis, cholestatic liver disease, and gastric bypass surgery, can predispose to VAD.

CLINICAL FINDINGS. The earliest manifestations of VAD are ocular changes. Impaired dark adaptation (nyctalopia) is followed by xerophthalmia, and as corneal keratin desquamates and overgrowth of *Xerosis bacillus* on the sclera occurs, white patches known as *Bitot spots* develop. Severe deficiency may lead to corneal xerosis, ulceration, and keratomalacia, which may result in corneal perforation, prolapse of the iris, and blindness (Fig. 130-5).

The cutaneous findings of VAD are the result of abnormal keratinization. Mild deficiency may manifest as xerosis and scaling, whereas more severe deficiency may result in deep skin fissuring referred to as *dermomalacia*. Squamous metaplasia of the salivary glands as well as the nasal and oral mucosa may occur, leading to xerostomia, hyposmia, and hypogeusia. Laryngeal, bronchial, and vaginal mucosa can also become involved. Phrynoderma, meaning "toad skin," is typically associated with VAD. These keratotic follicular papules often first develop on the anterolateral thighs and posterolateral upper arms, which then spread to extensory surfaces of the

▲ **FIGURE 130-5** Vitamin A deficiency, advanced keratomalacia, in a 5-month-old Arab child. Note hyperkeratosis of facial skin. Serum vitamin A level was 2 μg/dL (normal, 20 to 50 μg/dL).

▲ **FIGURE 130-6** Vitamin A deficiency. Typical perifollicular hyperkeratosis of the chest in a Tanzanian adult male.

extremities, shoulders, abdomen, back, buttocks, face, and posterior neck (Fig. 130-6). Although originally reported in association with VAD, phrynoderma is a non-specific finding that can be observed with deficiencies in B-complex vitamins and vitamins C and E, as well as EFA deficiency, PEM, and general malnutrition states.[25]

LABORATORY TESTING. Vitamin A levels can be measured from serum. Normal serum levels are typically between 20 and 50 μg/dL.

TREATMENT. The recommended daily allowance (RDA) of vitamin A is between 1000 and 5000 IU, with younger individuals requiring a lower intake of vitamin A. Recommended treatment for VAD is 100,000 to 300,000 IU of oral vitamin A daily until symptoms resolve and serum levels normalize.

Vitamin A Toxicity. **EPIDEMIOLOGY.** Vitamin A toxicity is the result of excess intake of vitamin A and can occur on an acute or chronic basis. Acute toxicity occurs when excessive amounts of vitamin A are ingested over a period of several hours or days. Toxicity typically results when intake exceeds 20 times the RDA in a child or 100 times the RDA in an adult. Chronic toxicity results from daily ingestion of greater than 25,000 IU for more than 6 years or greater than 100,000 IU for more than 6 months of pre-formed vitamin A. Children appear to be more sensitive to excess vitamin A intake than adults. Individuals most at risk for toxicity include patients taking systemic vitamin A derivatives for the treatment of dermatologic conditions such as acne, psoriasis, and ichthyosis. The other populations at risk include vitamin food faddists who consume large quantities of nonprescription vitamin A supplements.[26] Two notable episodes of vitamin A toxicity occurred in the 1950s when very high levels of vitamin A supplementation were added to infant formulas and the 1970s when high doses of vitamin A were used to treat a variety of dermatologic diseases.[27]

CLINICAL FINDINGS. Individuals with acute vitamin A toxicity have dry, scaly skin, with large areas of desquamation and fissuring of the lips and angles of the mouth. Other signs and symptoms include headache, fatigue, anorexia, nausea, vomiting, blurred vision, pseudotumor cerebri, myalgias, and arthralgias. An early cutaneous sign of chronic vitamin A toxicity in adults is dryness of the lips, which may progress to diffuse, dry, pruritic, scaly skin with peeling of palms and soles, alopecia, follicular hyperkeratosis, and hyperpigmentation of the face and neck. Anorexia, fatigue, and weight loss may also occur. It is interesting to note that follicular hyperkeratosis may occur in the settings of both VAD and toxicity.

In children, chronic toxicity presents as coarse hair with diffuse alopecia, coarse skin with generalized exfoliation, hyperpigmentation, and exfoliative cheilitis. Pseudotumor cerebri may cause headaches and papilledema, whereas infants may have a bulging fontanelle. Skeletal changes are common with vitamin A toxicity, and may present with growth retardation secondary to premature closure of the epiphyses and spontaneous bone fractures. Proposed mechanisms for the pathologic bone findings seen in vitamin A toxicity involve antagonism between vitamin A– and vitamin D–mediated intracellular signaling pathways and interactions with calcium-regulating hormones.[16,26] Deposition of excess vitamin A in adipose tissue and perisinusoidal fibrosis of the liver leading to cirrhosis are the most significant effects of long-term vitamin A toxicity.

LABORATORY TESTING. Laboratory findings in patients with hypervitaminosis A include elevated levels of vitamin A, serum calcium, and alkaline phosphatase (AP). This alteration in calcium homeostasis can lead to calcification of tendons, ligaments, and soft tissues. Deposition of excess vitamin A in adipose tissue and perisinusoidal fibrosis of the liver, which can lead to cirrhosis, are the most significant effects of long-term vitamin A toxicity.

TREATMENT. Almost all of the symptoms of vitamin A toxicity subside after the excess vitamin intake is discontinued, with the exception of liver cirrhosis and consequences of pseudotumor cerebri.

Carotenemia and Carotenoderma. **EPIDEMIOLOGY.** Although hypervitaminosis A is a disease that causes a broad spectrum of clinical findings, excessive intake of carotene results in a benign disorder characterized by yellow-orange skin pigmentation. The condition was described as "carotenemia" in 1919 by Hess and Meyers, who reported a connection between yellow skin pigmentation and increased serum carotene levels.[28] During World War I and World War II, carotenemia was more commonly seen because of the dietary shift from a meat-based diet to a more plant-based diet due to food shortages.

ETIOLOGY AND PATHOGENESIS. Carotenes are not synthesized endogenously and are obtained through intake of carotene-rich foods. Plant carotenes are converted to vitamin A in the gastrointestinal tract, but approximately one-third of carotene is directly absorbed. Several factors can affect carotene absorption, including thyroid hormone, pancreatic lipase and bile acid concentrations, processing of foods, and dietary fat and fiber content. Hypothyroid patients notice an elevation of carotene levels as a result of decreased conversion to retinol. Pancreatic lipase and bile acids digest carotene so that a deficiency of these enzymes due to pancreatic or biliary or hepatic dysfunction could result in elevated carotene levels. Mashing, cooking, and pureeing fruits and vegetables increase the availability of carotene because cell membranes are ruptured in the process, whereas dietary fiber decreases absorption. Because carotene is fat-soluble, a high-fat meal increases absorption. Patients with conditions that lead to hyperlipidemia, such as diabetes mellitus, nephrotic syndrome, and hypothyroidism, also are predisposed to carotenemia because of a linear relationship between the amount of β-lipoprotein and carotene. Impaired conversion of carotene to vitamin A in patients with hypothyroidism and liver disease further contributes to carotenemia. Some patients with anorexia nervosa can present with carotenemia because of increased intake of vegetables. Other groups at risk for carotenemia are food faddists; those with excessive intake of nutritional supplements, dried seaweed (nori), carrots, and papayas;

and infants ingesting a large amount of pureed vegetables.[29–31]

Clinical Findings. Excessive ingestion of carotenes does not result in hypervitaminosis A because the slow conversion of carotene to vitamin A in the intestinal mucosa is not rapid enough to produce toxic amounts of vitamin A.

Excess carotene deposits in the stratum corneum due to its high lipid content. The yellow discoloration of skin secondary to carotenemia is called *carotenoderma*. The carotene is excreted by sebaceous glands and in sweat, so the yellow pigmentation appears first on the face, predominantly in the nasolabial folds and forehead, and then becomes diffusely distributed, with accentuation on the palms and soles. The pigmentation is particularly noticeable in artificial light. Of note, carotenoderma, in contrast to jaundice, spares mucous membranes, including the sclera.

Laboratory Testing. Carotenemia does not occur until serum carotene levels reach three to four times normal levels or greater than 250 μg/dL and is detectable approximately 4 to 7 weeks after initiation of a carotenoid-rich diet.

Treatment. Treatment involves discontinuation of excessive carotene intake, and carotenoderma typically fades as the intake of carotene decreases.

VITAMIN D (CALCITRIOL)

Etiology and Pathogenesis. Vitamin D is essential for regulation of calcium and phosphorus metabolism. Vitamin D acts on the gastrointestinal tract to increase dietary calcium and phosphate absorption, stimulates increased bone resorption of calcium and phosphate, and stimulates the renal tubules to increase reabsorption of calcium and phosphate.

Humans obtain vitamin D from two sources: (1) dietary intake, and (2) synthesis in the skin from exposure to ultraviolet light. Common dietary sources of vitamin D include fortified milk, fish oil, and fishes such as salmon, sardines, herring, tuna, cod, and shrimp. Vitamin D can also be synthesized in the epidermis from the precursor molecule 7-dehydrocholesterol (provitamin D_3) by ultraviolet light in the 290- to 320-nm range. Previtamin D_3 then undergoes a spontaneous, temperature-dependent isomerization to vitamin D_3 (cholecalciferol), which enters the dermal capillaries. At this point, endogenous vitamin D_3 and exogenous dietary D_2 (ergocalciferol) undergo hydroxylation in the liver to 25-hydroxyvitamin D. This molecule travels to the kidney where it is again hydroxylated to make mature vitamin D (1,25-hydroxyvitamin D, also known as *calcitriol*).

The most common disorder of vitamin D metabolism is vitamin D–deficient rickets, which results from decreased dietary intake of vitamin D. Two types of vitamin D–dependent rickets have been described. Type I is an autosomal recessive disorder caused by a deficiency in renal vitamin D-1α-hydroxylase. Type II, also referred to as *hereditary vitamin-D–resistant rickets*, is a rare autosomal recessive disorder caused by mutations in the vitamin D receptor gene or, less commonly, by the production of a nuclear ribonucleoprotein that interferes with the ability of the vitamin D receptor to bind to DNA. Both types of vitamin D–dependent rickets result in end-organ resistance to physiologic levels of 1,25-hydroxyvitamin D.

Epidemiology. Although the earliest classic accounts of the clinical symptoms of rickets were published in 1645 by Daniel Whistler and in 1650 by Francis Glisson, it was not until 1861 that Trousseau of France hypothesized that rickets was caused by inadequate diet and sun exposure. During the Industrial Revolution, a combination of poor diet, smog and tall buildings that obscured the sun, and inadequate time outdoors all contributed to the persistence of rickets in the United States and Europe. By 1918, John Howland, Edward Park, and Paul Shipley had used rat models of rickets to identify the anti-rachitic molecule in cod liver oil as vitamin D.[26]

Vitamin D–deficient rickets continues to occur in modern times. A recent resurgence in vitamin D–deficient rickets has prompted further evaluation of those at risk.[27–29] Groups at risk for vitamin D deficiency include those with inadequate diet, malabsorption, and decreased exposure to sunlight. This includes the elderly or debilitated who have decreased sun exposure or decreased vitamin intake; patients on anticonvulsant therapy; those with malabsorption from gastrointestinal surgery, celiac disease, or pancreatic or biliary disease; and dark-skinned individuals living in areas with poor sun exposure. Rickets also occurs with greater frequency during puberty, when physical and behavioral changes modulate vitamin D availability and the demand for calcium, phosphorus, and vitamin D intake increases. In societies in which women are expected to cover their skin in public for cultural reasons, the scant opportunities for sun exposure increases the risk for vitamin D deficiency if dietary intake is insufficient to meet daily requirements.

Exclusively breast-fed infants, especially those with dark skin tones, may require vitamin D supplementation.[29] In the past, preterm infants were at risk for rickets because of an inadequate supply of calcium and phosphorus at the time of birth. Since the introduction of breast milk fortifiers and preterm formulas, the incidence of rickets of prematurity has decreased dramatically. In response to the continued increase in cases of vitamin D–deficient rickets, the American Academy of Pediatrics in 2003 outlined three populations who should be given supplemental vitamin D (200 IU): (1) all breast-fed infants unless they take in 500 mL/day of fortified formula or milk; (2) all non–breast-fed infants taking in less than 500 mL/day of fortified formula or milk; and (3) children and adolescents who do not obtain regular sun exposure, do not ingest at least 500 mL of fortified milk a day, or do not take a multivitamin with at least 200 IU vitamin D.[32] It appears that only limited sunlight exposure is necessary to produce adequate amounts of vitamin D_3. For patients with Fitzpatrick skin type II, it has been calculated that only 5 minutes of summertime noon sun two to three times weekly provides adequate vitamin D production to satisfy physiologic requirements.[33,34] Given the movement to encourage sunscreen use, there has been concern regarding secondary vitamin D deficiency. Chronic sunscreen use does decrease 25-hydroxyvitamin D, but with intermittent lapses in sunscreen application, there seems to be no significant impact on the incidence of vitamin D deficiency.

Clinical Findings. The classic clinical manifestations of vitamin D–deficient rickets are skeletal in nature. Calcium and phosphorus deficiency leads to poor calcification of new bones, resulting in fraying and widening of the metaphyses. This can be best appreciated at costochondral junctions of the anterior ribs, creating the well-known "rachitic rosary." Poor calcification of the skull bones results in craniotabes, a softening of the skull bones that gives them a ping-pong ball feel on palpation. As the bones become weaker, they cannot support the weight of the

child, and progressive lateral bowing of the lower extremities occurs. Other findings can include frontal bossing, widening of the wrists, scoliosis, hypotonia, fractures, dental defects, and, rarely, hypocalcemic seizures or tetany. Early radiographic signs of rickets include widening of the epiphyseal plate and blurring of the epiphyseal and metaphyseal junction. If the disease progresses, deformities at the growth plate develop, including cupping, splaying, formation of cortical spurs, and stippling. The bone cortices appear thinner, and generalized osteopenia is noted.

Vitamin D–dependent rickets type II has also been associated with cutaneous features that are clinically indistinguishable from the syndrome of generalized atrichia associated with mutations in the hairless gene.[35,36] In both conditions, affected patients are born with hair. However, within a few months after birth, scalp and body hair are lost, with the exception of eyebrows and eyelashes. Small papules and cysts representing abnormal, rudimentary hair structures characteristically develop on the face and scalp. These cysts typically show disintegration of the lower two-thirds of the follicular unit. Although the cutaneous features—notably the alopecia and cysts—are phenotypically and histologically identical, these are distinct clinical entities (Table 130-1).

Laboratory Testing. In addition to the clinical and radiologic signs of rickets, laboratory examination may be helpful. Elevated serum AP levels and low serum 25-hydroxyvitamin D levels are often useful laboratory indicators of vitamin D deficiency. In the early stages of rickets, parathyroid hormone levels increase to compensate for declining serum calcium levels, but this compensatory mechanism becomes inadequate if the deficiency continues.

Treatment. The recommended daily value of vitamin D is 5 to 10 μg. Treatment includes oral vitamin D repletion with dihydroxyvitamin D in addition to a calcium-rich diet. Supplementation with 200 to 400 μg vitamin D per day until resolution of symptoms, about 2 to 3 months, is usually adequate. Additional therapy can include judicious sun exposure.

VITAMIN E (TOCOPHEROL) Vitamin E is rarely associated with deficiency or excess states of disease. Vitamin E is found in oils and shortenings, as well as various fortified grains, dark green leafy vegetables, legumes, nuts, avocado, and small fishes such as herring and sardines.[37] Because it is a fat-soluble vitamin, excessive intake may augment the effects of anticoagulant medications, leading to purpura and propensity for hemorrhage.[38] Deficiency states are rare. However, ataxia with isolated vitamin E deficiency is a rare and severe spinocerebellar neurodegenerative disorder with autosomal recessive inheritance. Patients with mutations in the α-tocopherol transfer protein are unable to properly transfer vitamin E (α-tocopherol) from lysosomes into lipoproteins, which results in a predisposition to oxidative stress in affected cells and leads to neurologic degeneration.[39–41]

VITAMIN K (PHYTONADIONE) ***Etiology and Pathogenesis.*** Vitamin K is a necessary co-factor in the carboxylation of glutamate residues on coagulation factors II, VII, IX, X, and proteins C and S. Dietary vitamin K, phylloquinone, is found in green, leafy vegetables, certain legumes, soybeans, cereals, and beef liver. Phylloquinone is actively transported in the distal small bowel. Approximately one-half of the body's vitamin K is obtained though these dietary sources, and the other half is synthesized by gastrointes-

tinal flora as menaquinones, which are passively absorbed in the distal small bowel and colon.

Epidemiology. Vitamin K is so named after the Danish word "koagulationsvitamin," which literally translates to mean "clotting vitamin." Vitamin K deficiency beyond the newborn period is rare, but may result from malabsorption, liver disease, inadequate dietary intake, or medications. Fat malabsorption occurs in conditions such as regional ileitis, topical sprue, celiac disease, cystic fibrosis, pancreatic insufficiency, and biliary obstruction. Antibiotic use can result in vitamin K deficiency by altering the populations of normal bowel flora. Coumarin interferes with vitamin K epoxide reductase, an enzyme important in the recycling of inactive vitamin K into its active form. Other medications that can interfere with vitamin K metabolism include anticonvulsants (phenytoin), rifampin, isoniazid, high-dose salicylates, cholestyramine, and cephalosporins.[9,42]

Clinical Findings. Vitamin K deficiency leads to impaired coagulation and hemorrhage and can present in the neonatal period, when it is referred to as *hemorrhagic disease of the newborn* (HDN). Neonates are particularly prone to vitamin K deficiency because of poor transplacental transfer, low dietary intake, and a sterile bowel. HDN is divided into early presentation and late presentation. The incidence of early HDN is 0.25 percent to 1.7 percent and causes unexpected bleeding in the first week of life in an otherwise healthy neonate. It can present as ecchymoses, cephalohematomas, or nasal, subgaleal, umbilical, intestinal, or intracranial hemorrhages. Late HDN is defined by the American Academy of Pediatrics as unexpected bleeding from severe vitamin K deficiency in 2- to 12-week-old infants who are primarily breast-fed and who received no or inadequate neonatal vitamin K prophylaxis.[43] Vitamin K deficiency in older children and adults can present as purpura, ecchymoses, gingival bleeding, and gastrointestinal, genitourinary, and retroperitoneal hemorrhage.

Laboratory Testing. Because vitamin K is a key co-factor in the coagulation pathway, deficiency of vitamin K typically manifests as elevations in both prothrombin time and activated partial thromboplastin time. Serum levels of vitamin K can also be measured.

Treatment. Neonatal prophylaxis is traditionally administered as a single intramuscular dose of 0.5 to 1.0 mg of vitamin K. Several studies have evaluated the use of oral vitamin K prophylaxis, but there are no definitive data on efficacy, safety, or bioavailability.[43]

Acute treatment of vitamin K deficiency with hemorrhage is with fresh frozen plasma to replace deficient coagulation factors. Vitamin deficiency can also be treated with parenteral or intramuscular 5 to 10 mg vitamin K per day to correct severe deficiency.

Water-Soluble Vitamins

VITAMIN B_1 (THIAMINE) ***Etiology and Pathogenesis.*** Disorders of thiamine may have broad-ranging clinical implications because thiamine is an essential coenzyme for several enzymes involved in nicotinamide adenine dinucleotide phosphate (NADPH) synthesis, carbohydrate metabolism, and deoxyribose and ribose synthesis. Thiamine is used as a coenzyme for transketolase in the pentose phosphate pathway to produce NADPH. Thiamine pyrophosphate acts as a coenzyme in pyruvate dehydrogenase and α-ketoglutarate dehydrogenase, which are involved in oxidative decarboxylation reactions in the metabolism of carbohydrates and branched-chain amino acids.

Epidemiology. Thiamine is obtained from whole grains, enriched bread products, dried peas and beans, potatoes, and fish. Polished rice eliminates the thiamine-containing husk and predisposes to thiamine deficiency.

Disorders of thiamine excess are extremely rare. Most arise as a result of intravenous administration for suspected thiamine deficiency in the context of chronic alcoholism. Local irritation at the site of intravenous administration, generalized pruritus, and anaphylactic or anaphylactoid reactions have been described.[44] Neurotoxicity can occur in experimental settings when thiamine is administered directly into the central nervous system.[45] In general, thiamine excess states are extremely rare in humans.

Historically, the term *beriberi,* derived from Sinhalese meaning "extreme weakness," has been used to refer to thiamine deficiency. The symptoms of beriberi have been recognized in East Asian countries for thousands of years because polished white rice is a dietary staple.

Clinical Findings. Thiamine deficiency in the United States is now rare. Predisposing factors for pediatric thiamine deficiency include unsupplemented parenteral nutrition, breast-fed infants of thiamine-deficient mothers, congestive heart failure,[46] and severe malnutrition. Early signs include irritability, apathy, restlessness, and vomiting. As the disease progresses, neurologic signs of Wernicke encephalopathy may develop, such as ophthalmoplegia, ataxia, nystagmus, and characteristic laryngeal nerve paralysis resulting in aphonia, which is a classic manifestation of infantile beriberi. Other symptoms include congestive heart failure, tachycardia, dyspnea, and cyanosis. In 2003, a series of infants presenting with ophthalmoplegia as a manifestation of Wernicke encephalopathy was reported in Israel as a result of a thiamine-deficient infant soy formula. In all these cases, a prodromal illness was observed. Early symptoms included vomiting, anorexia, diarrhea, lethargy, irritability, and developmental delay. Upbeat nystagmus and ophthalmoplegia were the primary neurologic signs. After treatment, those with early disease had complete recovery, but those with severe disease had residual neurologic complications.[47]

Adult beriberi has been categorized into dry and wet forms. Dry beriberi describes a symmetric distal peripheral neuropathy involving both sensory and motor systems. Wet beriberi includes neuropathy and signs of cardiac involvement, including cardiomegaly, cardiomyopathy, congestive heart failure, peripheral edema, and tachycardia. A red, burning tongue and peripheral edema have also been observed with wet beriberi.

Laboratory Testing. Diagnosis of thiamine deficiency is made by measurement of erythrocyte thiamine transketolase or blood thiamine concentration. The more reliable measure is erythrocyte thiamine transketolase activity before and after thiamine pyrophosphate stimulation, represented as a percentage of thiamine pyrophosphate effect. Normal values are up to 15 percent.

Treatment. Because thiamine is a co-factor in a variety of metabolic pathways, daily thiamine requirements are calculated from an individual's ideal total caloric intake, with current recommendations of 0.5 mg per 1000 kcal.

Treatment of thiamine deficiency can be via intravenous, intramuscular, or oral routes of administration. Usually, treatment for beriberi is initiated with

intravenous or intramuscular thiamine of 50 to 100 mg per day for 7 to 14 days, then oral supplementation is provided until full recovery is documented.

VITAMIN B_2 (RIBOFLAVIN) ***Etiology and Pathogenesis.*** Riboflavin was discovered in 1879 as a fluorescent yellow-green substance found in milk. Riboflavin is used in two coenzymes, flavin mononucleotide (FMN) and flavin-adenine dinucleotide (FAD), both of which are involved in oxidation-reduction reactions in cellular respiration and oxidative phosphorylation. These two enzymes are also involved in pyridoxine (vitamin B_6) metabolism. Recent studies have suggested that riboflavin deficiency may contribute to increased plasma homocysteine levels, impaired handling of iron, and night blindness.[48]

Riboflavin is typically obtained through dairy products, nuts, meat, eggs, whole grain and enriched bread products, fatty fish, and green leafy vegetables. A small amount of dietary riboflavin is present as free riboflavin; most are found as FAD or FMN. Dietary FAD and FMN are hydrolyzed to riboflavin in the small intestines by brush border enzymes. Free riboflavin in the intestinal lumen is then taken up by active transport in the proximal small bowel.

Deficiency states can be caused by decreased intake, inadequate absorption, and phototherapy. Alcoholics, the elderly, and adolescents are groups at risk for riboflavin deficiency secondary to poor nutritional intake. In areas of India, China, and Iran, riboflavin deficiency is endemic as a result of their dependence on an unenriched cereal diet. Infants of riboflavin-deficient mothers are also at risk of deficiency because breast milk concentrations of the vitamin are proportional to maternal concentrations. Once weaned from the breast, these infants are at additional risk if they are not transitioned to milk. When confounded by PEM, riboflavin deficiency may be worsened because the usual renal compensatory mechanism of increased riboflavin absorption is impaired in this setting. Visible light phototherapy for jaundiced neonates causes photodecomposition of riboflavin.[49] Certain drugs also affect riboflavin levels through effects on absorption or metabolic inhibition. Chlorpromazine and other tricyclic drugs inhibit transport of riboflavin in the gastrointestinal tract, predisposing to deficiency states.[50] Borate displaces riboflavin from binding sites, increases urinary riboflavin excretion, and inhibits riboflavin-dependent enzymes, contributing to riboflavin deficiency.[51]

Clinical Findings. Signs of acute riboflavin deficiency include a deep red erythema, epidermal necrolysis, and mucositis. The severity of symptoms depends on the severity of deficiency.[52]

Clinical signs of chronic riboflavin deficiency or ariboflavinosis begin 3 to 5 months after initiation of an inadequate diet. Skin and mucous membrane findings predominate. Initially, angular stomatitis manifests as small papules at the corners of the mouth that enlarge and ulcerate before developing into macerated fissures that extend laterally and often bleed (Fig. 130-7). Pronounced cheilosis with erythema, xerosis, and vertical fissuring of lips can occur. Early glossitis appears as prominent lingual papillae, but after these papillae are lost, the tongue becomes smooth, swollen, and magenta in color. The dermatitis of riboflavin deficiency resembles seborrheic dermatitis in that it involves the nasolabial folds, nostrils, nasal bridge, forehead, cheeks, and posterior auricular regions. Flexural areas of the limbs may also be affected. Plugging of the sebaceous glands (dyssebacia) may be observed around the nose. The dermatitis can affect the genitalia, more often to a greater extent in males than in females. A red, confluent, crusty, or lichenified dermatitis of the scrotum often spreads to involve the inner thighs. In general, the dermatitis is worse in areas of chafing or trauma. Infants frequently manifest the dermatitis in the inguinal areas. In older individuals, the dermatitis is often more pronounced in facial creases and wrinkles, and, if incontinent, can involve the perianal and buttock areas. Cutaneous findings are not aggravated by light exposure, but are exacerbated by heavy physical activity. Ocular findings, in particular photophobia and conjunctivitis, are also a prominent feature of this. *Oculo-orogenital syndrome* is the term used to describe this constellation of symptoms.

▲ **FIGURE 130-7** Riboflavin deficiency. Angular stomatitis with maceration in an Arab child. Riboflavin excretion in the urine was diminished.

Laboratory Testing. A normochromic, normocytic anemia may be observed. Measurement of erythrocyte glutathione reductase activity can be used as a screening test, but a trial of riboflavin supplementation is often the most optimal method to confirm a riboflavin deficiency.

Treatment. The recommended daily intake of riboflavin is 0.6 mg per 1000 kcal. Treatment for deficient infants and children is 1 to 3 mg per day, and for adults, 10 to 20 mg.

VITAMIN B_3 (NIACIN) ***Etiology and Pathogenesis.*** Niacin (vitamin B_3) is a vitamin co-factor that can be obtained in the diet or synthesized endogenously from the essential amino acid tryptophan. Niacin is found in whole grains and enriched bread products, nuts, dairy products, liver, animal meat, mushrooms, and dried beans. Dietary niacin exists primarily in the form of nicotinamide adenine dinucleotide (NAD) and NADPH. NAD and NADPH are hydrolyzed in the intestinal lumen to form nicotinamide. Nicotinamide can be converted to nicotinic acid by intestinal bacteria or be absorbed into the bloodstream. Nicotinamide and nicotinic acid then travel to the liver, kidney, and intestines, where they are converted back to NAD and NADPH. These two agents act as hydrogen donors and acceptors in oxidation-reduction reactions involved in the synthesis and metabolism of carbohydrates, fatty acids, and proteins.

Epidemiology. Deficiency of niacin or vitamin B_3 results in pellagra. In 1735, Gasper Casal described a group of poor peasants in northern Spain who were particularly affected by a skin disorder referred to then as "mal de la rosa," so named because of the reddish, glossy rash on the dorsum of the hands and feet. He noted that these peasants were all poor, ate mainly maize, and rarely ate fresh meat.

Pellagra was endemic in the southern United States in the early 1900s because of a common diet consisting principally of cornbread, molasses, and pork fat. Pellagra remains endemic in parts of the world, including South Africa, China,

and India, where corn and maize continue to be a dietary mainstay. Corn and maize contain bound niacin, so without alkaline hydrolysis to release the niacin, it is unavailable for absorption. Jowar, a type of millet found in parts of India, contains adequate levels of niacin, but large quantities of leucine interfere with the conversion of tryptophan to niacin.[53] Although Mexicans have a predominantly maize-based diet, pellagra is relatively uncommon because preparation of the maize includes washing it in lime water, which releases the complexed niacin.

Because niacin is absorbed from the gastrointestinal tract, gastrointestinal disorders can predispose to pellagra. Impaired absorption of tryptophan and niacin occurs in patients with jejunoileitis, gastroenterostomy, prolonged diarrhea, anorexia nervosa, chronic colitis, ulcerative colitis, cirrhosis, Crohn disease, and subtotal gastrectomy.[54] Patients with Hartnup disease, a rare autosomal recessive disorder caused by a defective renal and intestinal transport of neutral amino acids such as tryptophan, develop pellagra-like symptoms in childhood. This is caused by a defect in the neutral brush border system, resulting in malabsorption of amino acids, including tryptophan.[55] Alcoholics develop pellagra from a combination of poor diet and malabsorption. Overly restrictive diets seen in patients with eating disorders, such as anorexia nervosa, presumed food allergies, or food faddism can also cause pellagra.

Patients with carcinoid syndrome are at risk for pellagra. Normally, about 1 percent of tryptophan is metabolized to serotonin, but in carcinoid syndrome, an excessive amount, about 60 percent, is converted to serotonin. Because of this diversion of tryptophan to serotonin production, less tryptophan is available to make niacin.

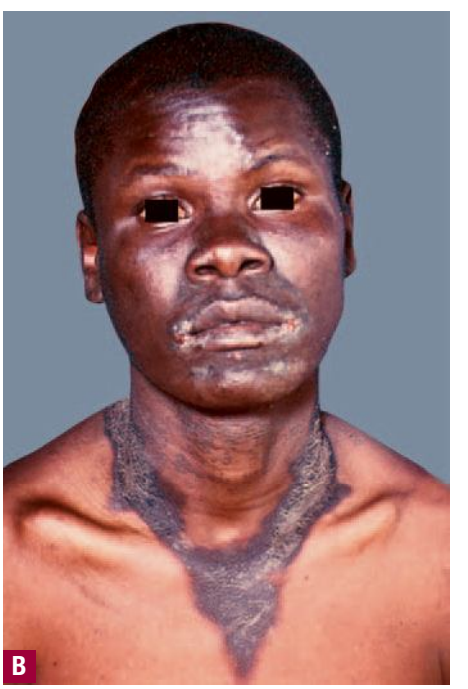
Medications can also induce symptoms of pellagra. Isoniazid is a competitive inhibitor of NAD because of their similar structures and also impairs pyridoxine functioning, which is essential for niacin synthesis from tryptophan. 5-Fluorouracil inhibits conversion of tryptophan to niacin, and 6-mercaptopurine inhibits NAD phosphorylase, which inhibits NAD production. Other implicated medications include phenytoin, chloramphenicol, azathioprine, sulfonamides, and antidepressants.[56]

Clinical Findings. Pellagra is classically described with the four Ds of dermatitis, diarrhea, dementia, and death. The characteristic photosensitive dermatitis begins as erythematous, painful, or pruritic patches. The skin becomes progressively more edematous, and several days later may develop vesicles and bullae that can rupture, leaving crusted erosions, or develop into brown scales (Fig. 130-8). Over time, the skin thickens into sharply demarcated, keratotic, hyperpigmented plaques. Painful fissures can develop in the palms and soles, resembling goose skin. The dorsum of the hands is the most commonly affected site, and when the rash extends proximally, more on the radial than ulnar side, it forms the "gauntlet" of pellagra. A butterfly distribution may be apparent on the face when it extends from the nose to the cheeks, chin, and lips. When the dermatitis affects the upper central portion of the chest and neck, it is referred to as "Casal's necklace." It can sometimes extend down over the sternum to create a "cravat." Mucous membrane involvement may manifest as cheilitis, angular stomatitis, glossitis, and ulceration of the buccal mucosa and vulva.

Gastrointestinal symptoms may represent the earliest signs of pellagra. Diarrhea, nausea, vomiting, abdominal pain, and anorexia have been reported. Neurologic symptoms, such as insomnia, fatigue, nervousness, apathy, impaired memory, and depression, can progress to psychosis and dementia in later stages. Without treatment, pellagra leads to death from multiorgan failure.

Laboratory Testing. Diagnosis is primarily made on clinical grounds and through a rapid response to vitamin supplementation. However, measurement of the urinary metabolites of niacin N-methylnicotinamide and pyridone may be used to aid in the diagnosis.

Treatment. The recommended daily value of niacin is 15 to 20 mg of niacin, or about 60 mg of exogenous tryptophan. Treatment with 500 mg per day of nicotinamide or nicotinic acid is given over



▲ **FIGURE 130-8** Pellagra. Acute dermatosis. **A.** "Glove" or "gauntlet" exudative and crusted lesions on the hands. **B.** "Casal's necklace" on the neck with facial involvement.

several weeks. Nicotinamide is preferred over nicotinic acid because nicotinic acid is frequently associated with headache and flushing. Neuropsychiatric symptoms may remit after 24 to 48 hours of treatment, but skin lesions often take 3 to 4 weeks to clear.[57]

VITAMIN B_6 (PYRIDOXINE) ***Etiology and Pathogenesis.*** Vitamin B_6 describes three interchangeable molecules: pyridoxine, pyridoxamine, and pyridoxal. Humans are unable to synthesize any of these molecules, but fortunately they are widely available in both plant and animal products. Meats, whole grains, vegetables, and nuts are the best sources for vitamin B_6. Processing of these foods can decrease the amount of available vitamin B_6 that is absorbed through passive diffusion in the jejunum. The most common form of vitamin B_6 is pyridoxal-5-phosphate. Vitamin B_6 is employed in multiple pathways, including the decarboxylation and transamination of amino acids, gluconeogenesis, conversion of tryptophan to niacin, sphingolipid synthesis, prostaglandin synthesis, and neurotransmitter synthesis. As such, clinical features of pyridoxine deficiency may overlap with those of niacin deficiency.

Epidemiology. Due to the availability of dietary vitamin B_6, deficiency is seldom caused by inadequate intake, but can occur in alcoholics due to poor diet. More commonly, causes are malabsorption and medication-induced deficiency. Small bowel disorders, such as Crohn disease and celiac disease, can interfere with vitamin B_6 absorption. Medications that have been implicated in causing deficiency include isoniazid, hydralazine, penicillamine, and oral contraceptives. Isoniazid, hydralazine, and penicillamine bind to pyridoxal-5-phosphate and increase excretion and/or decrease activity of the coenzyme.

Clinical Findings. Vitamin B_6 deficiency presents as a seborrheic-like dermatitis of the face, scalp, neck, shoulders, buttocks, and perineum. Clinical features resemble niacin deficiency, including photodermatitis, glossitis, and cheilitis. Glossitis appears as redness, burning, and ulceration of the tongue, leading to flattening of the filiform papillae. Other manifestations include angular stomatitis, cheilosis, and conjunctivitis. This condition produces an oculo-orogenital syndrome quite similar to that seen with riboflavin deficiency.[58] Somnolence, peripheral neuropathy, paresthesias, weakness, and confusion can occur. Other signs and symptoms are nonspecific, and include nausea, vomiting, depression, anorexia, and anemia. Vitamin B_6 deficiency often resembles pellagra because vitamin B_6 is needed for the conversion of tryptophan to niacin.

Vitamin B_6 toxicity from excessive intake does not typically produce skin findings, although it can be associated with peripheral neuropathy.

Laboratory Testing. Vitamin B_6 can be evaluated by mean measurement of plasma pyridoxal-5-phosphate. Low levels of plasma pyridoxal-5-phosphate indicate deficiency.

Treatment. Recommended daily values of pyridoxine depend on age and gender. Adult males require at least 2 mg per day; adult females require at least 1.6 mg per day; and infants require about 0.3 mg per day. Treatment involves discontinuation of inciting medication where relevant and initiating replacement therapy with 100 mg of pyridoxine per day. Oral lesions resolve in days, skin and hematologic changes resolve in weeks, and neurologic symptoms over several months.[9]

VITAMIN B_9 (FOLATE) ***Etiology and Pathogenesis.*** Folate can be found in almost all foods, particularly in liver, wheat bran and other grains, leafy green vegetables, and dried beans. Tetrahydrofolate, the coenzyme form of folate, is used for single-carbon transfers in amino acid, purine, and pyrimidine metabolism. Malabsorptive states (such as celiac disease, chronic diarrhea, status-post total gastrectomy) and antifolate medications (such as methotrexate, trimethoprim, oral contraceptives, and pyrimethamine) have been implicated in producing folate deficiency. The antiepileptics phenobarbital and phenytoin can also lead to folate deficiency states through induction of microsomal hepatic enzymes by anti-epileptics, which deplete folate stores.[59] The poor diets of alcoholics can produce folate deficiency. In children, folate deficiency can be also be associated with excessive boiling of milk or a goat's milk diet because of its low bioavailability of folate when compared with human or cow's milk.[60,61]

Clinical Findings. The primary manifestation is hematologic: hypersegmented neutrophils, macrocytosis, and megaloblastic anemia. Neutropenia, thrombocytopenia, diarrhea, and irritability may also be observed. In contradistinction to vitamin B_{12} deficiency, folate deficiency is not associated with neurologic symptomatology.

Mucocutaneous findings include glossitis with atrophy of the filiform papillae, angular cheilitis, mucosal ulceration, perirectal ulcerations, perineal seborrheic dermatitis, and diffuse brown hyperpigmentation concentrated in the palmar creases and flexures.[62,63]

Laboratory Testing. Macrocytic and megaloblastic anemia with hypersegmentation of neutrophils is suggestive. Diagnostic confirmation can be accomplished through measurement of serum folic acid levels.

Treatment. Folic acid supplementation is typically curative. Discontinuation of antifolate agents if implicated is recommended if involved. Ruling out concurrent vitamin B_{12} deficiency is crucial before initiating treatment for folate deficiency. If vitamin B_{12} deficiency is present but not treated, the hematologic symptoms may respond to folate, but the neurologic symptoms will progress. Treatment involves 1 to 5 mg of folic acid per day.

VITAMIN B_{12} (COBALAMIN) ***Etiology and Pathogenesis.*** Vitamin B_{12} is an important coenzyme for two biochemical pathways in humans. Methylcobalamin is a coenzyme for methyltransferase that converts methylate homocysteine to methionine, which is used in DNA, protein, and lipid metabolism. 5′-Adenosylcobalamin is required to catalyze the reaction by methylmalonyl coenzyme A (CoA) mutase to convert methylmalonic acid to succinyl-CoA, which is used in fat and carbohydrate metabolism.

Vitamin B_{12} is found primarily in animal products, with liver, eggs, milk, beef, and organ meats being excellent sources. Gastric acid separates vitamin B_{12} from food proteins so it can bind to intrinsic factor in the duodenum. This complex is taken up by specific ileal receptors in the terminal ileum. In the enterocyte, vitamin B_{12} dissociates from intrinsic factor and enters the portal circulation bound to transcobalamin II for transport to tissues. Between 1 percent to 5 percent of free cobalamin is absorbed along the intestinal wall by passive diffusion. The body is able to store large amounts of vitamin B_{12}, so symptoms of deficiency often take 3 to 6 years to develop.

Epidemiology. Causes of vitamin B_{12} deficiency can be divided into three groups: inadequate intake, malabsorption, and other. Elderly individuals and psychiatric patients with poor diets, and strict vegetarians and their breast-fed infants are most likely to become deficient from inadequate intake. Cases related to malabsorption can be further divided into four groups: decreased gastric acid states (chronic proton pump inhibitors and histamine H_2 receptor blockers), decreased intrinsic factor (pernicious anemia, atrophic gastritis, postgastrectomy), microbial competition in the gut (bacterial overgrowth, *Diphyllobothrium latum* infection), and impaired absorption (Crohn disease, Whipple disease, Zollinger-Ellison syndrome, celiac disease). The other causes of cobalamin deficiency relate to inborn errors of transport or metabolism.[64]

Clinical Findings. Vitamin B_{12} deficiency manifests primarily in four systems. As with cases of folate deficiency, mucocutaneous manifestations of vitamin B_{12} deficiency include glossitis, angular cheilitis, hair depigmentation, and cutaneous hyperpigmentation. Glossitis is characterized by an atrophic, red, and painful tongue with atrophy of the filiform papillae, which is referred to as *Hunter glossitis*. Hair depigmentation may be localized or diffuse. Hyperpigmentation can be diffuse and symmetric or involve a few scattered macules. The greatest concentration is usually observed on the hands, nails, and face, with the most commonly affected areas being the palmar creases, flexural regions, and pressure points. This hyperpigmentation often resembles Addison disease, but patients show no evidence of adrenal insufficiency.[65–68]

Three proposed hypotheses exist regarding the pathophysiology of the hyperpigmentation. Vitamin B_{12} maintains glutathione in reduced form, which is used to regulate tyrosinase, an enzyme necessary in melanogenesis. The first hypothesis is that, in vitamin B_{12} deficiency, increased tyrosinase activity results in hypermelanosis. Another proposed hypothesis involves defective melanin transport between melanocytes and keratinocytes. Finally, megaloblastic changes in keratinocytes from B_{12} deficiency may affect melanin distribution.[9,16,67,68]

Cobalamin deficiency can cause the neurologic manifestations of subacute combined degeneration of the dorsal and lateral spinal column. Generalized weakness with paresthesias progresses to ataxia and symmetric loss of vibration and proprioception, worse in the lower extremities, eventuating in severe weakness, spasticity, paraplegia, and incontinence. Other neurologic findings include apathy, somnolence, irritability, memory loss, dementia, and psychosis. Early neurologic findings may present before hematologic signs.

Laboratory Testing. The hematologic findings are similar to those found in folate deficiency, namely macrocytic anemia and hypersegmented neutrophils. Bone marrow biopsy reveals a hypercellular marrow secondary to disordered maturation.

Deficiency is diagnosed by measuring serum cobalamin levels, with levels less than 200 pg/mL indicating definite B_{12} deficiency and 200 to 300 pg/mL being borderline low.

Treatment. Treatment depends on treating the cause of deficiency and supplementing with vitamin B_{12}. Oral supplementation is not recommended due to poor absorption. For vitamin B_{12} deficiency in adults, supplementation with 30 μg administered via the intramuscular or subcutaneous route for 5 to 10 days, followed by 100 to 200 μg per month is recommended. In children, a dose of 100 μg/day for 10 to 15 days followed by 100 μg per week for several months may be required. For pernicious anemia, supplementation with cyanocobalamin at a dose of 1000 μg per week for 1 month administered via the intramuscular or subcutaneous route is usually sufficient. If symptoms persist, continued supplementation with 1000 μg of parenteral cyanocobalamin every month may be required.

VITAMIN C (ASCORBIC ACID) ***Etiology and Pathogenesis.*** Vitamin C is an antioxidant and essential co-factor in several biologic reactions, including collagen biosynthesis, prostaglandin metabolism, fatty acid transport, and norepinephrine synthesis. Humans are unable to synthesize ascorbic acid because they lack gulonolactone oxidase, an enzyme most other animals use to convert glucose to ascorbic acid.

The majority of dietary vitamin C is obtained from fruits and vegetables, like potatoes, tomatoes, berries, citrus fruits, and green vegetables. Vitamin C is absorbed in the distal small bowel. Most dietary vitamin C is completely absorbed, but absorption decreases as dietary intake increases. Depletion of body stores occurs after 1 to 3 months of a deficient diet.

As a water-soluble vitamin, ascorbic acid excess states are not typically associated with significant clinical disease. However, vitamin C deficiency is a disease of both great clinical importance and one of great historical significance.

Epidemiology and Pathogenesis. Scurvy, the disease of vitamin C deficiency, has been documented since antiquity. Ancient Greek, Roman, and Egyptian texts make reference to scurvy. Scurvy plagued sailors for hundreds of years before its cause was fully understood. George Anson's famous pursuit of Spanish ships in 1740 to 1744 began with more than 1400 crew members. By the end of the 4-year journey, he returned with only 145 of his original crew members, with 4 killed in enemy action and over 1300 having died from scurvy.[69]

In 1747, James Lind devised one of the earliest clinical trials to investigate crew members from the HMS Salisbury afflicted with scurvy and discovered that oranges and lemons were the most effective treatment for scurvy.[70] Although these findings were published in 1753, it was not until 1793 that lemon juice became a required daily provision on long sea voyages.[71]

As the incidence of scurvy decreased at sea, several epidemics on land occurred. The Great Potato Famine of 1845 to 1848 and World War I and II were times of nutritional impoverishment. The armies of the Crimean War and American Civil War, Arctic explorers, and California gold rush communities suffered from scurvy in large numbers. In the late nineteenth and early twentieth centuries, an explosion in cases of infantile scurvy occurred in the United States because of the trend toward heated milk and proprietary foods.[72] Heating or pasteurization of milk decreases its available vitamin C content.[73]

Causes of scurvy include insufficient vitamin C intake, increased vitamin requirement, and increased loss. Inadequate intake is the most common cause. Elderly individuals living alone may have limited diets as a result of poverty, immobility, poor dentition, poor access to groceries, or dementia.[74,75] Alcoholics, food faddists, individuals with presumed food allergies, and cancer patients may have decreased overall dietary intake or may simply avoid fruit and vegetables.[76] Iatrogenic scurvy occurs when physicians recommend dietary restrictions for certain conditions, such as in ulcerative colitis,

Whipple disease, peptic ulcers, and gastroesophageal reflux, or with inadequate vitamin supplementation with parenteral nutrition. Increased vitamin C requirements are encountered with certain drugs, including aspirin, indomethacin, tetracycline, oral contraceptives, corticosteroids, and tobacco smoking. Peritoneal dialysis and hemodialysis can induce scurvy because the water-soluble vitamin is removed during the dialyzing process[77] Scurvy has also been reported among patients receiving liver transplants.[78]

◀ **FIGURE 130-9** Vitamin C deficiency in an 18-year-old girl after gastrointestinal surgery. Note the "corkscrew" or "swan-neck" hairs associated with perifollicular purpura.

Clinical Findings. Ascorbic acid is required for the hydroxylation of proline residues on procollagen, allowing the formation of hydrogen–hydrogen bonding in the triple helix of mature collagen. Without ascorbic acid, the polypeptides are unstable and unable to form stable triple helices. This results in decreased collagen secretion from fibroblasts, increased collagen solubility, and unstable collage fibrils. This abnormal collagen creates pathology in skin, mucous membranes, blood vessels, and bone, leading to the four Hs of scurvy: *h*emorrhagic signs, *h*yperkeratosis of hair follicles, *h*ypochondriasis, and *h*ematologic abnormalities.

The earliest cutaneous sign of scurvy is phrynoderma—enlargement and keratosis of hair follicles, especially on the posterolateral aspect of the arms, resembling keratosis pilaris. The keratotic plugging generalizes, extending to the back, buttocks, posterior thighs, calves, and shins. The hairs within these plugged follicles become curled, resulting in corkscrew hairs (Fig. 130-9). The corkscrew hair results from impaired keratin cross-links by disulfide bonds. As the disease progresses, the follicles, red from congestion and proliferation of surrounding blood vessels, then turn purple, and finally red and hemorrhagic. This palpable perifollicular purpura is characteristically found on the legs. "Woody edema" of the lower extremities is associated with pain and ecchymosis. Other non-specific cutaneous findings include xerosis and acne. Poor wound healing and even dehiscence of old wounds in skin and bone can occur because vitamin C is necessary for wound healing and maintenance of healed wounds. Splinter hemorrhages in the nail bed can also occur.

Oral manifestations are common. Gingival disease manifests as swelling, ecchymoses, bleeding, and loosening of teeth. Interdental and marginal gingivae become red, smooth, swollen, and shiny before becoming purple, black, and necrotic. Existing gingivitis and poor dentition predispose to more severe disease, but those without teeth do not develop hemorrhagic gingivitis.

Hemorrhage can occur in areas other than the skin, mouth, and nails. Bone disease is a frequent manifestation in children. Hemorrhage can be intra-articular, intramuscular, and subperiosteal. This can lead to pain and disruption of the growth plates. Bowing of the long bones and a depressed sternum with an outward projection of the end of the ribs are noted on musculoskeletal examination. Metaphyseal spurs with marginal fractures (Pelkan sign), a ring of increased density surrounding the epiphysis (Wimberger sign), widening of the zone of provisional calcification (white line of Frankl), and a transverse band of radiolucency in the metaphysis (scurvy line or Trummerfeld zone) are seen on radiographs of extremities. Periosteal bleeding may occur. Epistaxis, hematuria, intracerebral hemorrhage, subconjunctival hemorrhage, and gastrointestinal hemorrhage have been reported. Weakness, fatigue, emotional lability, hypochondriasis, weight loss, arthralgias, hypotension, anorexia, and diarrhea are non-specific findings associated with vitamin C deficiency.

The causes of a normochromic, normocytic anemia are multifactorial, including blood loss from hemorrhage, intravascular hemolysis, intracellular iron depletion, and decreased folate levels.

Laboratory Testing. Scurvy is a clinical diagnosis, but when uncertain of the diagnosis, measurement of leukocyte ascorbate level can be helpful.

Treatment. Recommended daily intake of vitamin C is 40 to 60 mg of ascorbic acid. With vitamin C supplementation, clinical symptoms rapidly improve within several days after initiation of supplementation. Therapeutic doses of 100 to 300 mg of ascorbic acid are administered daily until symptoms completely resolve.

BIOTIN ***Etiology and Pathogenesis.*** Biotin is an essential co-factor for several carboxylating enzymes: acetyl-CoA carboxylase in fatty acid synthesis and lipogenesis; pyruvate carboxylase in gluconeogenesis; and propionyl-CoA and 3-methylcrotonyl-CoA carboxylases, both involved in amino acid catabolism.

Eggs, liver, milk, peanuts, mushrooms, chocolates, and hazelnuts are common sources of biotin. Release of protein-bound dietary biotin depends on pancreatic biotinidase. Free biotin diffuses across the gut to bind to plasma proteins. Because biotin is found in many dietary sources and can be synthesized by enteric bacteria, deficiency is uncommon. In 1941, Paul Gyorgy described that avidin in egg white bound and inactivated biotin, and, indeed, biotin deficiency can be induced by feeding normal volunteers raw egg white–rich diets. Individuals following fad diets high in raw egg whites can be at risk for deficiency.[79] Biotin deficiency may arise from long-term parenteral nutrition without biotin supplementation.[80] Individuals on unsupplemented parenteral nutrition and on long-term antibiotics are particularly at risk because the antibiotics eradicate biotin-producing enteric flora.[81] A series of biotin deficiency cases were reported in Japan secondary to an elemental infant formula without supplemental biotin.[57]

Clinical Findings. Symptoms can develop 3 to 6 months after initiation of unsupplemented parenteral nutrition or a raw egg white–rich diet, but appear earlier in infants because of the greater biotin re-

quirement for growth. The cutaneous manifestations are similar to those of AE and EFA deficiency. An erythematous, scaling, and crusting dermatitis usually begins around the eyes, nose, and mouth and continues to involve multiple periorificial areas, including the perianal region. Alopecia, conjunctivitis, and glossitis have also been associated. Neurologic findings include irritability, lethargy, paresthesias, hypotonia, developmental delay, and myalgias. Nausea and anorexia have also been described.

Two inborn errors of metabolism, both autosomal recessive multiple carboxylase deficiencies, also alter normal biotin metabolism and may manifest with features of biotin deficiency as well as other systemic findings.

Laboratory Testing. If dietary history does not adequately explain findings suggestive of biotin deficiency, consultation to evaluate for inborn errors of metabolism is recommended. Biotinidase levels, serum amino acids, urine organic acids, carnitine studies, and ammonia may be helpful in differentiating this disorder from other metabolic diseases.

Treatment. The recommended daily value increases from 30 μg in neonates to 100 to 200 μg in adults. Acquired deficiency is treated with 150 μg of biotin per day until resolution of symptoms.

Minerals

IRON Iron is used in several biologic pathways, including heme synthesis, oxidation-reduction reactions, collagen synthesis, and as a co-factor for enzymes such as succinic dehydrogenase, monoamine oxidase, and glycerophosphate oxidase. Iron is found in red meats, egg yolks, dried beans, nuts, dried fruits, green leafy vegetables, and enriched grain products.

Iron deficiency remains an international problem that crosses socioeconomic and ethnic divides. Deficiency states result from inadequate intake or chronic blood loss. Groups at high risk include infants, menstruating females, and individuals with chronic gastrointestinal bleeds. Infants on an iron-fortified formula are at risk for deficiency 3 to 6 months after transitioning to cow's formula because of the lower iron content of cow's milk.[82]

Changes seen in iron deficiency involve the skin, mucous membranes, hair, and nails. Moderate iron deficiency causes fragile, longitudinally ridged, lamellated, or brittle nails. As deficiency progresses, the nail plate shows thinning, flattening, and a spoon-shaped convexity known as *koilonychia*. The index and third fingernails are usually the most severely involved. Even after iron replacement therapy begins, koilonychia resolves slowly. Hair changes include lusterless, brittle, dry, and focally narrow or split hair shafts, likely caused by impaired keratin production. Heterochromia of black scalp hair with alternating segments of dark brown, white, and silver bands has been described. Hair loss has been associated with iron deficiency.[83,84] However, the role of iron deficiency in hair loss continues to be a controversial topic.[85,86]

Mucous membrane manifestations include aphthous stomatitis, angular stomatitis, glossodynia, and absent or atrophied tongue papillae. Blue sclerae that persist after iron replacement are likely secondary to impaired collagen synthesis. Generalized pruritus of variable severity has been reported in some individuals with iron deficiency and is sometimes associated with dermatitis herpetiformis. Plummer-Vinson syndrome is an iron deficiency–associated syndrome encountered predominantly in middle-aged women with microcytic anemia, dysphagia, glossitis, koilonychia, and angular stomatitis. This is considered to be a pre-cancerous phenomenon, associated with carcinoma of the mouth or upper respiratory tract.

Iron deficiency in a microcytic anemia is diagnosed by measurement of serum iron levels, ferritin, total iron binding capacity, and transferrin saturation as well as free or zinc protoporphyrin levels. Treatment involves appropriate iron supplementation.

Chronic iron overload, hemosiderosis, can be associated with tissue injury, which is called *hemochromatosis*. Hyperpigmentation and ichthyosis-like changes of the skin are seen. Associated findings are cirrhosis of the liver, diabetes mellitus, and cardiomyopathy.

ZINC Zinc is an important micronutrient that is an essential component of many metalloenzymes involved in a variety of metabolic pathways and cellular functions, and is particularly important in protein and nucleic acid synthesis. Adequate zinc levels are also important for wound healing and for T-cell, neutrophil, and natural killer cell function. Zinc homeostasis depends on adequate zinc absorption and maintenance of appropriate intracellular and extracellular zinc levels. Dietary sources of zinc include meat, fish, shellfish, eggs, dairy products, and legumes, with the highest and most bioavailable forms of zinc found in meats, fish, and shellfish. Other vegetables, fruits, and refined carbohydrates contain very little zinc. Phytates (found in cereal grains, legumes, and nuts) and fiber interfere with intestinal zinc absorption. Human breast milk contains very high levels of zinc during the first 1 to 2 months of lactation, averaging 3 mg/L; subsequently, zinc levels decrease. Human breast milk also contains a zinc-binding ligand that increases the bioavailability of breast milk zinc. Although cow's milk formula contains higher levels of zinc, the bioavailability is significantly less than that in human breast milk.

Enteral zinc absorption occurs in the small intestine. Zinc excretion occurs primarily via the gastrointestinal tract via pancreatic and intestinal secretions, with lesser amounts excreted in the urine complexed to free amino acids. Two important families of zinc transporter proteins, including 9 ZnT (zinc transporter) genes and 15 Zip (Zrt- and Irt-like proteins) transporters, have been identified in humans.

Although total body zinc is stored primarily in the bones, muscles, prostate, and skin, there is no free exchange of stored zinc, and metabolic needs must be met by a continued supply of dietary zinc. In plasma, approximately 50 percent of the total zinc is complexed with albumin, while the remainder is bound to other serum proteins, including transferrin and α_2-macroglobulin, or bound to free amino acids. Plasma levels may decrease transiently in response to intercurrent illness, surgery, or other stressors. Excess plasma zinc levels inhibit copper absorption, possibly through competitive inhibition of a common divalent cationic transporter. Zinc deficiency also results in impaired mobilization of hepatic retinol stores and is associated with impaired night vision (nyctalopia). Conversely, excessive calcium intake can interfere with normal zinc absorption, likely also a result of competitive inhibition.

Zinc Deficiency. **EPIDEMIOLOGY.** Zinc deficiency occurs worldwide. Populations at special risk include patients with intestinal malabsorption syndromes, liver disease, anorexia nervosa or food faddism, extensive cutaneous

burns, and nephrotic syndrome. Iatrogenic zinc deficiency may result from prolonged parenteral or enteral nutrition that contains inadequate zinc levels to meet metabolic demands. Certain rural populations with diets high in phytates, as have been reported in certain parts of Iran, Turkey, and Yugoslavia, are also at risk for acquired zinc deficiency.

▲ **FIGURE 130-10** **A.** Patient with acrodermatitis enteropathica. These clinical findings resolved within 2 weeks of initiating zinc supplementation. **B.** This crusted and scaly, erosive, and sharply demarcated eruption appeared shortly after weaning. The child was highly irritable, whining and crying, and had diarrhea.

ETIOLOGY AND PATHOGENESIS. Zinc deficiency may be either inherited or acquired. The inherited form of zinc deficiency, AE, classically presents during infancy on weaning from breast milk to formula or cereal, which have lower zinc bioavailability than breast milk. These infants have a defect in an intestinal zinc transporter, the human ZIP4 protein, which prevents appropriate enteral zinc absorption.[87–89] There is a form of acquired zinc deficiency that may also present during infancy but, in contrast to AE, these infants become symptomatic while breast-feeding and improve after weaning to formula or table foods. Many of these reported infants have been premature, but cases have also been reported in full-term infants. The mothers of these infants have a presumed defect in mammary excretion of zinc into their breast milk, resulting in inadequate zinc intake in their infants.[90–92] Measurement of breast milk zinc levels is diagnostic when less than 70 μg/dL.

Acquired zinc deficiency may result from states associated with inadequate intake, impaired absorption, or increased excretion, including pregnancy, lactation, extensive cutaneous burns, generalized exfoliative dermatoses, food faddism, parenteral nutrition, anorexia nervosa, and even excessive sweating. Intestinal malabsorption syndromes, such as inflammatory bowel disease and cystic fibrosis, result in impaired intestinal absorption of zinc, whereas alcoholism and nephrotic syndrome result in increased renal zinc losses. Penicillamine has been reported to cause zinc deficiency in a patient with Wilson disease. Ornithine transcarbamylase deficiency has also been associated with zinc deficiency.

CLINICAL FINDINGS. AE presents soon after weaning in affected infants or during the fourth to tenth week of life in infants who are not breast-fed. The classic features of AE include alopecia, diarrhea, lethargy, and an acute eczematous and erosive dermatitis favoring acral areas—perioral, periocular, anogenital, hands, and feet (Fig. 130-10). The cutaneous findings are highly characteristic and often present initially as a nonspecific, acrally distributed, symmetric, eczematous dermatitis. Over time, bullae and erosions with a characteristic peripheral crusted border develop. Patients also appear to be predisposed to systemic infections as a result of impaired cell-mediated immunity, and superinfection with *Candida albicans* and bacteria, usually *Staphylococcus aureus*, is common. Delayed wound healing, acute paronychia, conjunctivitis, blepharitis, and photophobia may also be observed. Diarrhea may be prominent but is not seen in all cases. If untreated, the disease is fatal. Acute zinc deficiency secondary to impaired absorption of zinc, inadequate intake, or excessive renal or intestinal losses may result in a clinical picture that resembles AE and occurs also in adults (Fig. 130-11).

A chronic or subacute form of zinc deficiency is also recognized. These patients often have zinc levels in the mildly deficient range (40 to 60 μg/dL). Clinical manifestations include growth retardation in children and adolescents, hypogonadism in males, dysgeusia, poor appetite, poor wound healing, abnormal dark adaptation, and impaired

▲ **FIGURE 130-11** Zinc deficiency. **A.** There are plaques of dry, scaly, eczematous skin around the buttocks. The lesions often become secondarily infected with *Candida albicans*. **B.** Hands. The fingers are enlarged, and there are paronychia and bright erythema on the terminal phalanges.

mentation. Cutaneous manifestations, when present, are usually less striking and present predominantly as a psoriasiform dermatitis involving the hands and feet and, occasionally, the knees.

Laboratory Testing. A low plasma zinc level is the gold standard for diagnosing zinc deficiency. Use of contaminated needles, catheters, and sample tubes may lead to erroneously high measured zinc levels. Contact with collection tubes with rubber stoppers should be avoided as they may contain high levels of zinc. Hemolyzed samples are also inaccurate, as red blood cells contain very high zinc levels and cell lysis releases zinc. Normal plasma zinc levels range from 70 to 250 μg/dL. Measurement of serum AP—a zinc-dependent enzyme—is another useful indicator of zinc status, as AP may be low even when plasma zinc levels are low-normal; serum AP will increase with zinc supplementation, thus confirming the diagnosis.

In cases in which the plasma zinc level is equivocal and the diagnosis is uncertain, skin biopsy for routine histology may be helpful. The characteristic features are variable psoriasiform hyperplasia with confluent parakeratosis, spongiosis and pallor of the upper epidermis, focal dyskeratosis, and variable epidermal atrophy, These findings, however, are not specific; any may be seen in a number of other nutritional deficiencies.

Treatment. Zinc supplementation with either an enteral or parenteral formulation is appropriate. Clinical response is usually rapid, with initial improvement noted within several days. Although several zinc formulations are available, the most commonly used enteral formulation is zinc sulfate. Zinc chloride is recommended for parenteral supplementation.

In children, 0.5 to 1.0 mg/kg of elemental zinc given as one to two daily doses is recommended for mild to moderate zinc deficiency. Higher doses may be required in cases of acquired zinc deficiency due to intestinal malabsorption. In adults, 15 to 30 mg of elemental zinc per day is usually sufficient in cases of acquired zinc deficiency. Serum zinc levels should be monitored during therapy. Patients with AE require lifelong treatment. Patients with acquired zinc deficiency may need variable levels of supplementation, depending on their underlying disease. Of note, excess zinc levels may interfere with copper metabolism.

Zinc Toxicity. Zinc toxicity has been reported with exposure to zinc-containing fumes, intravenous poisoning, and ingestion of large amounts of zinc. There are no cutaneous manifestations. Severe vomiting, nausea, lethargy, dizziness, neuropathy, and dehydration. Hypocupremia may result.

COPPER

Copper is an essential component of several metalloenzymes, including tyrosinase and lysyl oxidase. Tyrosinase is involved in melanin biosynthesis, and lysyl oxidase deaminates lysine and hydroxylysine in the first step in collagen cross-linking. Other copper enzymes are involved in catecholamine production, free radical detoxification, and oxidation-reduction reactions.

Copper is found in fish, oysters, whole grains, beef and pork liver, chocolate, eggs, and raisins.

Copper Deficiency. Copper deficiency is uncommon, but can result from malnutrition, malabsorptive states, chronic unsupplemented parenteral nutrition, infants with a strictly cow's milk diet, and excessive intake of antacids, zinc, iron, or vitamin C, which can interfere with absorption. Celiac disease, cystic fibrosis, and short bowel syndrome lead to malabsorption of dietary copper.

Clinical manifestations in these cases include hypopigmentation of hair and skin and bony abnormalities (osteoporosis, fractures, periosteal reaction, and flaring of anterior ribs).

Microcytic anemia, neutropenia, hypocupremia, and hypoceruloplasminemia can be observed. Neutropenia is the earliest and most common sign of copper deficiency and is a sensitive measure of treatment adequacy. Treatment is with supplemental copper in the diet.

Copper and Menkes Disease. Menkes disease, also known as *kinky hair disease*, was described by John Menkes in 1962 as a multifocal degenerative disease of gray matter. Menkes originally described five male infants born into an English-Irish family who all showed an X-linked syndrome of neurologic degeneration, particular hair, and failure to thrive. The incidence of Menkes disease ranges from 1 in 100,000 to 1 in 250,000 live births. The Menkes gene, MNK, has been identified on chromosome Xq13. The protein product is a copper-transporting P-type adenosine triphosphatase, which is expressed in almost all tissues, except the liver. Mutations in MNK lead to decreased concentrations of copper because of impaired intestinal absorption and consequent decreased activity of cuproenzymes.[59,60]

Classically, signs of Menkes disease begin at 2 to 3 months of age, although neonatal indicators include preterm labor, large cephalohematomas, hypothermia, hypoglycemia, and jaundice. The characteristic facies of Menkes disease is a cherubic appearance with a depressed nasal bridge, ptosis, and reduced facial movements. By 2 to 3 months of age, there is loss of developmental milestones, hypotonia, seizures, and failure to thrive. Structural changes in the hair are seen (see Chap. 86), with the general appearance of short, sparse, lusterless, tangled, and depigmented hair. The eyebrows have the same steel wool appearance as scalp hair. On light microscopy, pili torti is classically seen. Monilethrix, segmental shaft narrowing, and trichorrhexis nodosa, small beaded swelling of the hair shaft with fractures at regular intervals, may also be observed. Other cutaneous findings include follicular hyperkeratosis and soft, inelastic, depigmented skin, especially at the nape of the neck, axillae, and trunk. A high arched palate and delayed tooth eruption may be noted on oral examination.

Neurologic deficits represent the major morbidity in this disorder. Profound truncal hypotonia with poor head control is typical, and appendicular tone may be increased. Deep tendon reflexes are hyperactive. Suck and cry remain strong. Optic disks are pale with impaired visual fixation and tracking. Hearing remains normal. Developmental arrest occurs at occasional smiling and babbling. Bony changes most often involve the extremities and the skull, and, less often, the thorax, vertebrae, and pelvis. They include osteoporosis, metaphyseal widening and lateral spur formation, ossification of sutures, a diaphyseal periosteal reaction, scalloping of the posterior aspects of the vertebral bodies, and subperiosteal new bone formation. Renal involvement as hydronephrosis, hydroureter, and diverticula of the bladder can occur.

Elongation and tortuosity of many large vessels lead to severe arterial disease, a frequent cause of death by the age of 3 or 4 years.

The condition is identified by clinical history, physical examination, and reduced levels of serum ceruloplasmin and copper. Early treatment with copper histidinate has resulted in good outcomes, including normal neurodevelopmental

milestones, in some patients. Initiation of therapy in older patients may be helpful in the alleviation of symptoms such as irritability and insomnia.[93,94]

SELENIUM Selenium is an essential component of glutathione peroxidase, an antioxidant. Selenium is found in seafood, red meat, egg yolks, grain products, and chicken. The amount of selenium available in cereal grains depends on the selenium content of the soil where it was grown. Selenium deficiency in humans is endemic in the Keshan region of China where low selenium levels are present in soil.[95,96] Selenium deficiency can also occur in the context of restricted protein diets, unsupplemented parenteral nutrition, malabsorption states, and increased losses.[97,98] Two disorders have been attributed to selenium deficiency: Keshan disease and Kaschin-Beck disease. These diseases have only been reported in endemic areas of Asia.

Keshan disease is a multifocal myocarditis leading to fatal cardiomyopathy that is seen primarily in women and young children in endemic areas. Acute or chronic insufficiency of cardiac function, cardiomegaly, arrhythmias, and electrocardiographic abnormalities have been noted. Muscle pain and weakness with hepatic congestion, mesenteric lymphadenosis, erythrocyte macrocytosis without anemia, and pancreatic exocrine dysfunction have also been seen. Cutaneous findings in these patients have included white nail beds, similar to those of Terry's nails in hepatic cirrhosis, and hypopigmentation of skin and hair (pseudoalbinism). These findings resolve with selenium supplementation. Kaschin-Beck disease is an osteoarthropathy that affects the epiphyseal and articular cartilage and the epiphyseal growth plates, resulting in enlarged joints and shortened fingers and toes. Diagnosis of selenium deficiency is through measurement of plasma selenium levels and glutathione peroxidase activity. Selenium supplementation is used for both acute correction and long-term maintenance.

Selenium toxicity can be acutely fatal. Cases of toxicity have been associated with increased soil selenium and overdose through supplements. In the 1960s, reports of selenium toxicity came out of Enshi County in Hubei, China. The cause of this endemic toxicity arose from selenium-contaminated fertilizer products.[99] Sporadic cases of selenium intoxication secondary to excess supplement ingestion have been reported.[100] Hair becomes dry and brittle in association with an exfoliative dermatitis on the scalp, often resulting in broken hairs and alopecia. Nails also become brittle, with white horizontal streaking on the surface. Breaks in the wall of the nail eventually lead to nail loss. The new nail is fragile and thickened with a rough surface. Nails, hair, and teeth can all develop a reddish hue. Skin on the extremities and neck can become red, swollen, blistered, and, occasionally, ulcerate, which heals slowly. Neurologic complaints of peripheral anesthesia, hyperreflexia, numbness, convulsions, and paralysis have been reported. Nausea, vomiting, diarrhea, garlic or sour-milk breath odor, and hypersalivation can occur. Screening of plasma can be used to document elevated selenium levels. Treatment involves removal of the source of excess selenium.

MANGANESE Manganese activates glycosyltransferases used in the synthesis of glycosaminoglycans and glycoproteins and is used in two metalloenzymes (pyruvate carboxylase and superoxide dismutase). Manganese is also found in high concentrations in melanocytes. Reported cases of manganese deficiency are rare. Manganese deficiency was reported during a study of vitamin K requirements, when a study subject was accidentally placed on a manganese-deficient diet. He developed a mild dermatitis, reddening of his black hair, slowed hair and nail growth, and occasional nausea and vomiting with moderate weight loss. A subsequent study of manganese-deficient states showed no hair changes, but miliaria crystallina developed in half the subjects and disappeared after repletion. Long-term parenteral nutrition without adequate supplementation can induce manganese-deficient states.[101] Likewise, in cases in which manganese is supplemented in parenteral nutrition, hypermagnesemia can occur and has been associated with neurologic sequelae.[102]

NOMA (CANCRUM ORIS)

Noma (necrotizing ulcerative stomatitis, stomatitis gangrenosa, or cancrum oris), first described in 1848 by Tourdes,[103] is a devastating gangrenous condition that destroys soft and hard tissue of the face that predominantly affects young children between the ages of 1 and 4 years. "Noma" originates from the Greek word *nome*, which means to graze or to devour, which reflects the rapid progression of this condition. As public health initiatives improved sanitation in developed countries, the global epidemiology of noma likewise improved. Noma has become a rare occurrence in developed countries and is predominantly encountered now only in parts of Africa, Latin America, and Asia, although intermittent epidemics of noma have been reported.[104] In response to reports from humanitarian organizations, the WHO declared noma a health priority in 1994. The WHO estimates the worldwide incidence of noma to be 500,000 cases per year, with a 79 percent mortality rate. Unfortunately, the data on the incidence of noma are likely an underestimation of the true incidence, as less than 10 percent of affected individuals actually seek medical care.[105]

An increase in noma has been observed in developed countries over the last two decades, mostly in association with immunosuppressive therapy, human immunodeficiency virus/acquired immunodeficiency syndrome, and severe combined immunodeficiency.[106]

Malnutrition and deficiencies in vitamins A, B_6, C, and E; trace elements iron and zinc; and amino acids cysteine, methionine, serine, and glycine have been identified as possible contributing factors to immune dysfunction. Adrenal hyperfunction in PEM has also been implicated in depression of cell-mediated immunity and a decrease in mucosal resilience. Early malnutrition and chronic infections due to early weaning from breast milk may also represent predisposing factors.[107]

Noma appears to be a polymicrobial infection, with *Prevotella intermedia* and *Fusobacterium necrophorum* being the two most frequently isolated organisms.[108] Other frequently identified organisms are *Tannerella forsynthesis*, *Peptostreptococcus micros*, *Campylobacter*, streptococci, and enteric gram-negative rods. Although organisms are isolated from noma lesions, there is a low likelihood of transmissibility. There are no reports of outbreaks in families or villages after one child develops noma. Groupings of noma seem to be more associated with common risk factors rather than true transmission.

Parents often describe initial fever and apathy. Early acute noma often presents with soreness of the mouth, halitosis, tenderness of the lip or cheek, cervical lymphadenopathy, and purulent oral discharge. The intraoral lesion is a necrotizing stomatitis generally starting on the alveolar margin and extending to the mucosal surface of the cheek. This evolution is rapid, taking 24 to 48 hours.

▲ **FIGURE 130-12** Cancrum oris (noma). Massive destruction of the face in a Tanzanian child.

Swelling and blue-black discoloration of the skin overlying the intraoral lesion develops and rapidly becomes necrotic with well-defined borders. As it becomes black, this necrotic zone expands and forms a classic cone shape, cone gangreneux, with internal destruction greater than external involvement (Fig. 130-12). Laboratory investigation often shows severe anemia, a high white blood cell count, and hypoalbuminemia.

Acute necrotizing gingivitis, a painful inflammation and necrosis of the interdental papillae, was the precursor to noma. Progression to necrotic stomatitis and noma can occur if appropriate dental hygiene and antibiotics are not initiated. Acute necrotizing gingivitis is associated with poor oral hygiene, stress, and malnutrition. However, any oral mucosal ulceration or trauma, including tooth eruption and viral ulcers, can develop into noma.[109]

Noma neonatorum is thought to be a related but separate entity from noma. Gangrenous lesions appear on patients' noses, eyelids, oral cavities, anal regions, and genitalia in apparent response to *Pseudomonas aeruginosa* isolated from skin lesions and many of their blood cultures. This condition is almost uniformly fatal. Clinical experience indicates that preterm and low-birth-weight newborns, especially those with severe intrauterine growth retardation, are at greatest risk. The causative organism is usually *Pseudomonas*, but *Escherichia coli*, klebsiella, and staphylococci have occasionally been isolated. Because most cases of noma neonatorum are caused by *Pseudomonas*, it is possible that this represents a severe form of ecthyma gangrenosum.[110] Almost all reported cases have been from India, China, Lebanon, or Israel, but there was one reported case in the United States in 2002, and the vast majority (98 percent) of affected children were impoverished, living in very poor homes with an average of seven children per family.[111]

Healing lesions of noma are also difficult to manage because of extensive fibrous scars. These scars can lead to strictures of the mouth, severe dental malposition, defective speech, and even complete closure of the mouth from contractures. Management of acute noma is geared toward minimizing damage, but invasive intraoral procedures are contraindicated. Key goals of acute management are:

1. Correction of dehydration and electrolyte imbalances.
2. Treatment of predisposing disease (i.e., malaria, measles, human immunodeficiency virus, tuberculosis).
3. Antibiotics: some researchers recommend broad-spectrum antibiotics, whereas others believe that metronidazole is adequate as anaerobic organisms predominate.
4. Oral hygiene with chlorhexidine digluconate rinses.
5. Nutritional rehabilitation: oral, enteral, or parenteral.
6. Local wound care.
7. Physiotherapy: to reduce strictures from fibrous scarring.

Surgical intervention should not occur until the acute phase has ended, and is aimed at restoring function and improving appearance to allow patients to reintegrate into society.

CONCLUSION

Nutritional disorders arise most commonly as a result of nutrient deficiencies, but may also derive from imbalances in nutrients or at times from nutrient excess. Because macronutrients and micronutrients play roles in multiple biochemical pathways, these disorders often present with clinical features in a variety of organ systems. The key to diagnosis is in having a familiarity with the range of clinical presentations associated with these disorders and maintaining an appropriate index of suspicion for these disorders when evaluating dermatologic patients with skin findings or a history that might suggest a nutritional etiology.

CHAPTER 131

Cutaneous Changes in Errors of Amino Acid Metabolism

Peter H. Itin
Lowell A. Goldsmith

Inborn errors of amino acid metabolism are inherited defects of enzymes that result in important disturbance in amino acid biology.[1] Most of them are autosomal recessive disorders. Amino acids are the molecular units that make up proteins, and all proteins are various combinations of 20 specific naturally occurring amino acids.

Diseases of amino acid metabolism may lead to multiorgan disorders with signs and symptoms of mental retardation and dysfunction in numerous additional organs, including skin and hair.[2] With more sophisticated diagnostic techniques, metabolic diseases have gained increasing importance, and numerous rare entities have been identified, including hyperphenylalaninemias, hypertyrosinemias, disorders of histidine metabolism, disorders of proline and hydroxyproline metabolism, hyperornithinemias, dysfunctions of urea cycle enzymes, disorders of lysine metabolism, disorders of branched-chain amino acid and keto acid metabolism, disorders of transsulfuration with homocystinuria and homocystinemia, sarcosinemia, and non-ketotic hyperglycinemia.

Several diseases have important cutaneous manifestations that might be a clue to diagnosis (Table 131-1). An example of such a key manifestation representing errors of amino acid metabolism is acrodermatitis acidemica. These patients have characteristic cutaneous lesions that are similar to those in acrodermatitis enteropathica (see Chap. 130). Psoriasiform dermatitis on the trunk and extremities may occur together with diffuse alopecia and brittle hair.[4] In general, acral dermatitis with perioral erythema and desquamation is associated with poor feeding, lethargy, hypotonia, vomiting, and dehydration. Patients often have progressive neurologic symptoms. Patients with branched-chain aminoacidopathies may have methylmalonic acidemia, propionic acidemia, glutaric acidemia, biotinidase deficiency, multiple carboxylase deficiency, or maple syrup urine disease, all

TABLE 131-1
Inherited Disorders of Amino Acid and Organic Acid Metabolism with Skin Manifestations

Disease	Skin Manifestations	Deficient Enzyme/Pathophysiology (Mode of Inheritance)
Alkaptonuria	Ochronosis Black cerumen, eccrine, and apocrine secretions	Homogentisic acid oxidase (AR)
Argininosuccinic aciduria	Trichorrhexis nodosa Rough skin	Argininosuccinase (AR)
Aspartylglycosaminuria	Thick skin Coarsening of face Sagging skinfolds Increased acne Photosensitivity	Aspartylglycosamidase (AR)
Biotinidase deficiency	Erythematous rash Alopecia Oral candidiasis Seborrheic dermatitis Glossitis	Biotinidase (AR)
Citrullinemia	Light, short hair with interrupted cuticle	Argininosuccinate synthetase (AR)
Hartnup disease	Pellagra-like lesions Photosensitivity	Defect of neutral amino acid transport in renal and intestinal brush border (AR); increases excretion of tryptophan metabolites
Histidinemia	Light-colored hair and eyes	Histidase (AR)
Holocarboxylase synthetase deficiency	Seborrheic dermatitis Alopecia	Holocarboxylase synthetase (AR)
Homocystinuria	Fine, sparse, friable hair Thin skin Livedo reticularis Malar flush Vascular occlusions Marfanoid habitus	Cystathionine β-synthetase (AR)
Hydroxykynureninuria	Chronic stomatitis Ulcerated gums, gingivitis Photosensitivity	Kynureninase (AR)
Hyperprolinemia	Ichthyosis	Proline oxidase (AR)
Iminodipeptiduria (prolidase deficiency)	Chronic skin ulcers Recurrent infections	Prolidase (AR)
Isovaleric acidemia	Odor of sweaty feet, alopecia	Isovaleryl–coenzyme A dehydrogenase (AR)
Methionine malabsorption syndrome	White hair Dried celery or oasthouse odor Edema	Defective methionine transport
Phenylketonuria	Hypopigmentation Atopic dermatitis Scleroderma	Phenylalanine hydroxylase (AR) Dihydropterine reductase Defective dihydropterine synthesis
Tyrosinemia II	Painful, acral erosions Hyperkeratosis Corneal/conjunctival plaques and erosions	Tyrosine aminotransferase (AR)
Xanthurenic aciduria	Urticaria	Kynureninase (AD)

AD = autosomal dominant; AR = autosomal recessive.

of which are sometimes accompanied by cutaneous problems.

In general, all patients with acrodermatitis acidemica have absolute missing enzyme activity of their autosomal recessive mutated gene. Diagnosis is confirmed by documentation of increased amounts of amino acids in the urine. Exact diagnosis is the first step for adequate treatment of these diseases.

Hartnup disease results from a deficiency of neutral amino acid transport within the kidneys and small intestine and leads to pellagra-like features in a photodistribution (see Chap. 130). Neurologic deficiencies and reduced mental skills are often associated. The treatment of choice is nicotinamide.

TYROSINEMIAS

The genetic tyrosinemias are characterized by the accumulation of tyrosine in body fluids and tissue.[5,6] Tyrosine is a semi-essential amino acid, derived from the liberation of tyrosine from hydrolysis of dietary or tissue protein, or from the hydroxylation of the essential amino acid phenylalanine, and is the starting point for the synthesis of catecholamines, thyroid hormones, and melanogenesis. There are three types of tyrosinemia. The skin is not involved in tyrosinemia types I and III, but it is involved in tyrosinemia II, which is also called the *oculocutaneous tyrosinemia* and *Richner-Hanhart syndrome* [Online Mendelian Inheritance in Man (OMIM) #276600]. Tyrosinemia II is a rare distinctive clinical symptom complex involving the eyes, skin, and central nervous system and is potentially treatable. Tyrosine levels are elevated because of a deficiency of hepatic tyrosine aminotransferase (TAT).

Clinical Features

Approximately 100 patients with this clinical syndrome have been reported. Goldsmith and Reed were the first to correlate the oculocutaneous syndrome with an underlying tyrosinemia.[7] All patients had tyrosinemia, phenolic aciduria, and inflammatory skin and eye lesions. The sexes are affected equally, and the disease is worldwide in distribution. Transmission of tyrosinemia II is autosomal recessive. Consanguinity has been documented, and occurrence in several siblings within a family is well known (pseudodominant pattern). Heterozygotes are unaffected clinically and demonstrate no biochemical alterations of tyrosine or its metabolites in blood or urine.

TYROSINEMIA AT A GLANCE

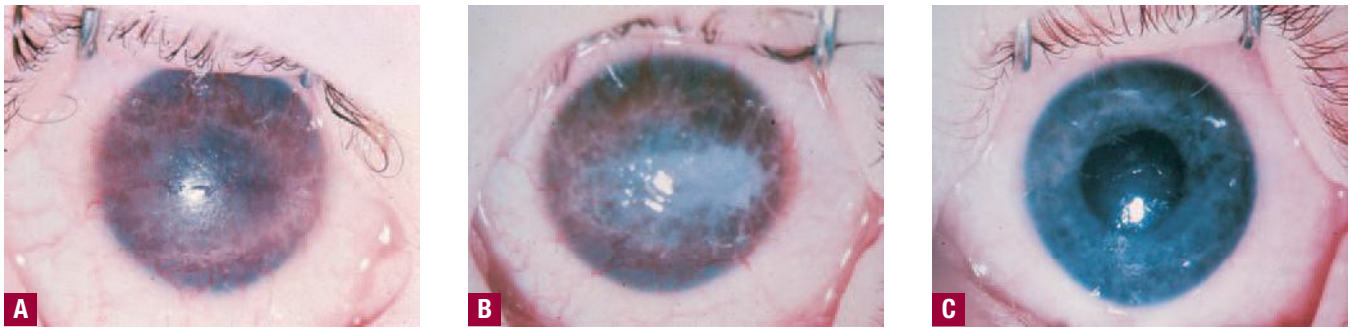
- Approximately 100 cases are reported worldwide.
- Tyrosinemia is an autosomal recessive disease induced by a deficiency of cytoplasmic tyrosine aminotransferase related to a defect on chromosome bands 16q22.1-22.3 (Online Mendelian Inheritance in Man #276600).
- Dermatologic manifestations include focal/diffuse palmoplantar keratosis with erosions, bullae or erythema, hyperhidrosis, and painful corneal erosions with photophobia; 50 percent of patients have mental retardation.
- Diet restriction of phenylalanine and tyrosine leads to amelioration of cutaneous symptoms and eye lesions.
- Differential diagnosis includes other forms of palmoplantar keratodermas and herpetic keratitis.
- Prenatal diagnosis is possible by amniocentesis with tyrosine aminotransferase assay and DNA analysis.

DERMATOLOGIC FEATURES Patients have hyperkeratotic yellowish skin lesions limited to the palms and soles, which in 80 percent of cases occur on the peripheral pressure-bearing areas.[5,7] Lesions usually begin during the first year of life. The skin lesions are painful, nonpruritic, and frequently associated with hyperhidrosis (Fig. 131-1). Diffuse plantar keratoderma and self-mutilation have been observed in individuals with tyrosinemia II.[8] Leukokeratosis of the tongue has been reported. Bullous lesions may occur and progress rapidly to erosions; these then become crusted and hyperkeratotic.[9] The fingertips and hypothenar eminences are commonly involved. Rare patients have hyperpigmentation and/or hyperkeratotic subungual lesions, and in older persons hyperkeratosis in the elbows, knees, and ankles may appear.[2]

OPHTHALMOLOGIC FEATURES The most important manifestations of oculocutaneous tyrosinemia are those involving the eye, because they can lead to permanent visual impairment.[10] Eye lesions occur weeks to months before the skin lesions. Ophthalmologic symptoms start as early as the first day of life and as late as 38 years of age. Tearing, redness, pain, and photophobia are early signs and symptoms; late findings include corneal clouding and central or paracentral opacities, which are initially intraepithelial and can progress to superficial or deep pseudodendritic keratitis (Fig. 131-2). Slit-lamp examination may reveal some degree of corneal ulceration, and occasionally birefringent crystals of tyrosine may be observed. Neovascularization is prominent. The eye disease occurs in 75 percent of affected patients and may lead to scarring, nystagmus, and exodeviation. Ocular symptoms may show spontaneous remission and recurrences and may occur independently of other manifestations. Topical therapy is ineffective, and herpes simplex virus and bacterial cultures consistently yield negative results.

NEUROLOGIC FEATURES Mental retardation of varying degrees is reported in half the cases, as is normal mental development. Hyperactivity has been observed in several affected children, as

▲ **FIGURE 131-1** Hyperkeratotic (**A**) and erosive (**B**) lesions in a patient with tyrosinemia II.



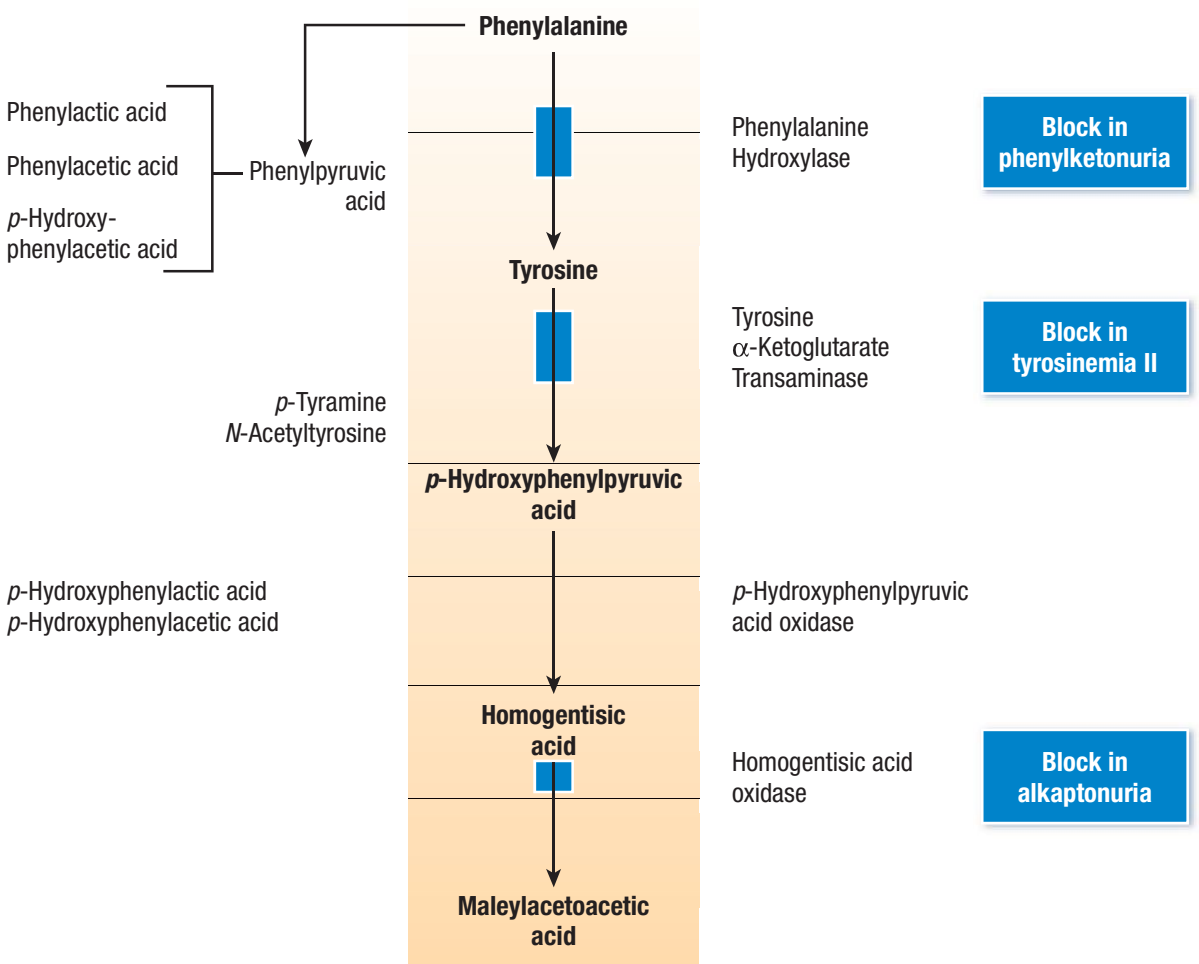
▲ **FIGURE 131-2** Corneal changes in tyrosinemia II. **A.** Cornea before treatment (left eye); corneal opacity and neovascularization are prominent. **B.** The right eye has even more extensive involvement. **C.** After 6 weeks of therapy, there is marked clearing of the lesions.

has abnormal language development. Untreated tyrosinemia II during pregnancy may be associated with mental retardation or seizures in the children resulting from that pregnancy.[11]

Laboratory Findings

AMINO ACID ABNORMALITIES In establishing the diagnosis in a child with tyrosinemia II, laboratory verification of plasma amino acid and urine organic acid levels is mandatory. The blood and urine tyrosine levels of affected patients are markedly elevated. Levels of other amino acids are not increased. Urinary tyrosine metabolite levels are elevated; these include *p*-hydroxyphenylpyruvic acid, *p*-hydroxyphenyllactic acid, *p*-hydroxyphenylacetic acid, and *N*-acetyltyrosine (Fig. 131-3). All these metabolic effects are consequences of the deficiency of hepatic TAT. A fluorometric procedure exists as well as a tandem mass spectrometry, which is used for neonatal screening.

TAT is a pyridoxal phosphate–dependent cytoplasmic enzyme that transaminates tyrosine, forming *p*-hydroxyphenylpyruvate (PHPPA). The human *TAT* gene contains 12 exons and transcribes a 2.75-kb messenger RNA (mRNA) that codes for a 454–amino acid protein.[5] The liver is the richest source of TAT; this specific TAT is not present in skin. In tyrosinemia II, the liver biopsy specimen shows little or no soluble TAT, although there is normal or slightly increased mitochondrial tyrosine (aspartate) transami-



▲ **FIGURE 131-3** Metabolic pathway of phenylalanine, tyrosine, and their derivatives.

nase activity.[12,13] Mitochondrial aspartate aminotransferase using tyrosine as a substrate produces increased amounts of PHPPA from the increased amounts of tyrosine available in tyrosinemia II. Because mitochondria do not have PHPPA oxidase activity, PHPPA and its metabolic products increase and appear in the urine, which creates the unusual situation in which metabolites are increased both proximally and distally to the defective enzyme.

HISTOPATHOLOGY Routine histopathologic analysis of the skin is not diagnostic; it shows hyperkeratosis, parakeratosis, and acanthosis.[9] In some cases, electron microscopy studies have shown lipid droplets in the cornified layer, increases in tonofibrils and keratohyalin, very tightly packed microtubular and microfibrillar masses, and minute tyrosine crystals in keratinocytes and Merkel cells.[14]

GENETICS Mutations occur in the human *TAT* gene, which results in high levels of tyrosine. *TAT* maps to the q22-q24 region of chromosome 16 and has been sequenced.[5] Multiple point mutations scattered throughout the *TAT* gene have been associated with tyrosinemia II.[15]

PATHOPHYSIOLOGY OF THE SKIN AND EYE LESIONS IN TYROSINEMIA II

Differential Diagnosis (Box 131-1)

Corneodermatoosseous syndrome (OMIM #122440), an autosomal dominant symptom complex of volar keratosis and keratitis that is clinically similar to tyrosinemia II, has been described in one family.[20] The lesions were more extensive than those in the classic Richner-Hanhart syndrome. In addition, brachydactyly with short distal phalanges, short stature, and soft teeth may occur.

Box 131-1

Differential Diagnosis of Tyrosinemia

Main Features

- Eyes
  - Herpetiform corneal ulcers
- Skin
  - Punctate, painful palmoplantar keratoderma on weight-bearing areas
- Neurologic features
  - Mental retardation
  - Hyperactivity

Consider

- Palmoplantar keratoderma with associated features
  - Corneodermatoosseous syndrome

Always Rule Out

- Eyes
  - Viral and bacterial infection
- Skin
  - Other forms of keratodermas, acquired or genetic

Treatment

With consumption of a low-tyrosine, low-phenylalanine diet (Mead Johnson, Tyromex-Ross), there is a rapid decrease in tyrosine to normal levels (30 to 90 μ*M*). Skin and eye lesions cleared within days and weeks in all individuals treated with the diet[7,12] (see Fig. 131-2C; Fig. 131-4; Box 131-2).

Some patients have responded objectively to etretinate, although plasma tyrosine levels remained unchanged.[21] In none of the patients studied has there been a response to cortisone acetate, ascorbic acid, pyridoxine, or folic acid, which are co-factors or known inducers of TAT and PHPPA oxidase. Surgical treatment is recommended for palmar lesions but not for the plantar form.

Box 131-2

Treatment of Tyrosinemia

- Low-tyrosine, low-phenylalanine diet
- Etretinate systemically

Because the consequences of tyrosinemia II are serious and a safe treatment is available, a patient presenting with any atypical bullous or hyperkeratotic disease on the palms and soles in the first months of life should be screened for tyrosine and its metabolites; screening tests are available in most hospital laboratories.[22] Amino acid analysis is necessary to confirm the diagnosis and follow the response to diet therapy. Dietary control in pregnancy should be recommended. A patient with tyrosinemia II was reported who had undergone two untreated pregnancies. During the pregnancies, plasma tyrosine level was raised, and the infants were retarded. On the other hand, several normal children of mothers with the disease have been observed.[23]

PHENYLKETONURIA

Phenylketonuria (phenylpyruvic oligophrenia, PKU) is an autosomal recessive disorder of aromatic amino acid metabolism (OMIM #261600) in which phenylalanine cannot be converted to tyrosine. PKU is caused by a deficiency of hepatic phenylalanine hydroxylase or co-factors for phenylalanine hydroxylase. There are additional causes that may lead to hyperphenylalaninemias, and eight subtypes have been described. Maternal PKU may lead to hyperphenylalaninemia. Unless the mother follows a special diet, the child is at risk to develop the typical signs and symptoms of PKU. Defects of biopterin metabolism, prematurity, liver disease, use of medications such as methotrexate, and high-protein diets may produce findings similar to those in PKU. Genotype-based prediction and

▲ **FIGURE 131-4** **A.** Diffuse plantar hyperkeratosis in an adult with tyrosinemia. **B.** The hyperkeratosis cleared on a low-tyrosine, low-phenylalanine diet without topical treatment.

PHENYLKETONURIA AT A GLANCE

- Autosomal recessive disorder induced by phenylalanine hydroxylase deficiency (Online Mendelian Inheritance in Man #261600). Gene on chromosome bands 12q22-24.1; incidence of 1 in 10,000 live births among Europeans.
- Clinical features include mental retardation, generalized hypopigmentation, blond hair, blue eyes, eczematous rash, vomiting in infancy, hyperactivity and seizures, mousy odor.
- Diagnosis is confirmed by a positive result on urinary ferric chloride test.
- Treatment consists of restricting phenylalanine in the diet.
- Differential diagnosis includes albinism, Chédiak-Higashi syndrome, and scleroderma.
- Prenatal diagnosis is possible by chorionic villus sampling/amniocentesis, measurement of metabolite levels, and DNA analysis.

classification of the biochemical phenotype is now possible in the majority of newborns with hyperphenylalaninemia.[24]

Epidemiology

The prevalence of PKU varies markedly in various countries. The highest incidence of PKU is found in Ireland and Scotland (1 in 4000), whereas in Finland only 1 in 40,000 births are affected. The overall frequency among northern Europeans was calculated to be approximately 1 in 10,000 and in the United States classic PKU was estimated to occur in approximately 1 in 11,000 births in the white population. Among blacks the frequency was estimated to be only approximately 1 in 50,000.

Clinical Features

The clinical hallmarks of PKU are mental retardation, diffuse hypopigmentation, seizures, eczematous dermatitis, and photosensitivity.[26] Newborns appear to be normal and develop manifestations of psychomotor alterations between 4 and 24 months of age. Early symptoms include heavy vomiting. The most important defects are marked mental retardation with irritability, hyperactivity, self-destructive behavior, hypertonicity, and seizures. Peculiar gait and increased deep tendon reflexes are noted. Microcephaly, brain calcification, and cataracts are observed quite commonly. Typically a mousy odor induced by phenylacetic acid is noted in urine and sweat.

Early infantile eczema, indistinguishable from atopic dermatitis, may be one of the first signs of PKU and occurs in 20 percent to 50 percent of affected infants during the first year of life. Later on, the incidence may be even higher. Dramatic clearing of eczema and seborrheic dermatitis with a low-phenylalanine diet has been reported in some patients, and a potential role for altered biotin recycling is suggested.[27] A further skin clue in PKU is pigment dilution, with impressive pale pigmentation, blond hair, and blue eyes seen in 90 percent of patients. The pigment dilution is reversible with phenylalanine restriction. The color changes may be especially striking in the rare black or Japanese patient with PKU, whose eye or hair color may be very different from that of other members of the ethnic group. The increased levels of phenylalanine and its oxidation products (phenylpyruvic acid, *o*-hydroxyphenylacetic acid, phenylacetic acid) inhibit the enzyme tyrosinase and therefore reduce melanization.[28]

Patients develop moderate photosensitivity. Edematous scleroderma of the extremities, which spares the hands and feet, is characteristic.[29] Plaque, guttate or generalized morphea, and atrophoderma of Pasini and Pierini (see Chap. 62) as well as lichen sclerosus et atrophicus (see Chap. 63) have been observed in PKU.[30]

Diagnosis

Diagnosis of PKU is made by documenting elevated levels of phenylalanine in the serum (20 mg/dL or higher, 10 to 50 times the normal level). Plasma tyrosine levels may be normal or elevated. In addition, elevated urinary phenylpyruvic acid levels can be documented. Additional laboratory abnormalities include phenylalanine hydroxylase deficiency, phenylpyruvic acidemia, and increased urinary levels of *o*-hydroxyphenylacetic acid and phenylacetylglutamine. Increased urinary levels of phenylpyruvic acid can be detected by a typical green coloration of urine after addition of 10 percent ferric chloride. In numerous countries PKU screening is performed in the neonatal screening program either by the semi-quantitative bacterial inhibition assay method in which several drops of capillary blood may show an elevated level of phenylalanine in a microbiologic procedure (Guthrie test) or by a quantitative chemical reaction method (Quantase test).[31] In affected babies, serum phenylalanine levels begin to rise on the third or fourth day of life. Prenatal diagnosis is possible by performing amniocentesis or chorionic villus sampling with identification of the gene. In addition, preimplantation genetic diagnosis for PKU made possible the birth of PKU-free children.[32]

Pathophysiology and Histology

The classic type of PKU is induced by a deficiency of phenylalanine hydroxylase or its co-factor tetrahydrobiopterin and a consequent accumulation of the precursor phenylalanine. The normal phenylalanine-tyrosine ratio is 1:1, whereas in PKU it is more than 3:1. It is widely believed that the pigment dilution is a result of the inhibitory effect of phenylalanine on tyrosinase. Biopsy specimens show increased fibroblasts and histiocytes and atrophy of skin appendages. The elastic fibers are scanty and fragmented and are thus different from those found in true scleroderma. Histologic examination shows a normal number of melanocytes but a decrease in mature melanosomes.

Differential Diagnosis

Atopic dermatitis and scleroderma as primary disorders must be distinguished from PKU (Box 131-3). Premature infants and individuals with liver disease

Box 131-3

Differential Diagnosis of Phenylketonuria

Main Features

- Skin
  - Pale pigmentation, dry skin and eczema, scleroderma-like lesions, fair hair
- Eyes
  - Blue eyes
- Neurologic features
  - Mental retardation
  - Seizures
  - Irritability and increased deep tendon reflexes

Consider

- Other disorders of amino acid metabolism with neurocutaneous features

Always Rule Out

- Atopic dermatitis
- Scleroderma

Box 131-4

Treatment of Phenylketonuria

- Low-phenylalanine diet
- Fish oil supplementation, which seems to improve visual evoked potentials
- Tyrosine supplementation (?)
- New phenylalanine-free formulas
- Reduction of phenylalanine uptake with purified phenylalanine ammonia-lyase
- Recombinant or pegylated phenylalanine ammonia-lyase
- Tetrahydrobiopterin supplementation to increase phenylalanine hydroxylase activity
- Large neutral amino acids supplementation to compete for blood-brain barrier carriers

may also show elevated plasma levels of phenylalanine.

Treatment

With a low-phenylalanine diet, which should probably be followed for life, the skin color, photosensitivity, odor, and eczema are reversible. In addition, early diet can dramatically reduce mental retardation, and if the blood phenylalanine levels are maintained at reasonable levels in early childhood, normal to low-normal intelligence can be expected[33] (Box 131-4). However, rigorous control of diet can lead to protein deficiency and an eczematous dermatitis.

ARGININOSUCCINIC ACIDURIA

Definition and Clinical Features

Argininosuccinic aciduria (ASA; OMIM #207900) is an autosomal recessive disorder of the urea cycle. Its incidence is estimated to be 1 in 70,000. ASA is characterized by hepatomegaly, mental retardation, seizures, episodic lethargy and ataxia, and friable, brittle hair with the morphology of trichorrhexis nodosa (see Chap. 86). The deficiency of an essential cytosolic enzyme in the urea cycle, argininosuccinase (argininosuccinate lyase), causes citrullinemia and an increase in blood ammonia. Argininosuccinate is increased in the blood and spinal fluid and is excreted in large amounts (2 to 9 g/day) in the urine.

The detailed clinical and biochemical features of the disease and the principles of therapy are reviewed by Nyhan, Barshop, and Ozand.[2] The hair abnormality is more characteristic of the late-onset disease, but in the early cases this peculiar type of alopecia brought the first patients to clinical attention.[38] Weaning and a change to a diet with a higher protein content can be precipitating factors in clinical disease. Essential to current therapeutic regimens are diets providing adequate energy, protein, and arginine.

The molecular pathology of the nucleic acids in this disease has been clarified, but the detailed pathophysiology of the hair defect remains to be determined.

Hair Defects

CLINICAL AND MORPHOLOGIC FEATURES[42]

About half the reported patients have had abnormally friable hair with visible trichorrhexis nodosa (see Chap. 86); the other half have had grossly normal hair. Brushing and combing accentuate breaking (i.e., brittle hair). No definite correlation can be made between liver argininosuccinase level, argininosuccinic acid levels, arginine levels, and the degree of hair abnormalities; some patients with severe ASA have had seemingly normal hair. Some patients' hair has improved with diet or without specific therapy. Hair shafts may show pseudo-trichothiodystrophy under polarizing microscopy with the typical dark and light banding.[43] Diet reverses grooving and abnormal polarization of hair shafts in argininosuccinase deficiency.[44] Eyelashes, eyebrows, and general body hair, as well as the nails, may be involved.

MOLECULAR NATURE OF HAIR DEFECTS

The basic nature of the hair defects is not known.

Increasing arginine in the diet aids hair growth and structure in this disease, which suggests that the decrease in arginine may be related to the defective hair. Because the urea cycle is depressed in ASA, the arginine required for protein synthesis would come predominantly from dietary sources. Hair protein is rich in arginine (up to 10 percent of the amino acid residues are arginine); furthermore, the citrulline present in certain specialized proteins in the medulla and internal root sheath is derived from arginine.

Other Disorders of the Urea Cycle[30]

In citrullinemia (OMIM #215700), a rare recessive disease caused by the absence of argininosuccinic acid synthetase, there is somatic and mental retardation and increased levels of citrulline in blood, urine, and cerebral spinal fluid; low to normal values of plasma arginine; and increased blood ammonia levels. Hair in such patients may be brittle, breaking easily. Microscopically, plucked hairs may be flattened, may be twisted through 180 degrees on their own axes, and may show breakage at the point of twisting.[47] Irregular areas of dystrophy and interruption of the cuticle were observed.

Deficiency of the cytosolic enzyme argininosuccinic acid synthetase is associated with trichorrhexis nodosa. Its overall clinical presentation is almost identical to that of ASA, although the plasma citrulline levels are usually higher (more than 1 m*M*) in the former disease. Enzymatic and genetic analyses confirm the diagnosis.

Diagnosis

Retardation, ammonia intolerance, and abnormal hair will suggest these syndromes. The diagnosis is confirmed by high-voltage electrophoresis or ion-exchange chromatography of the urine, blood, or spinal fluid. Only a tiny percentage of the cases of trichorrhexis nodosa and brittle hair are due to ASA. Prenatal diagnosis is possible after chorionic villus sampling or amniocentesis to ensure the birth of unaffected infants.[40]

ALKAPTONURIA

Alkaptonuria (OMIM #203500), or homogentisic acid oxidase (HGO) deficiency, is a rare metabolic disorder. Excessive homogentisic acid (HGA) is excreted in the urine, which often turns dark, and HGA accumulates in connective tissues, including the dermis[49] (ochronosis).

Epidemiology

Alkaptonuria is inherited as an autosomal recessive trait. Pedigrees suggestive of a dominant mode of transmission contain a high degree of consanguinity and, when subjected to careful scrutiny, are actually found to show pseudodominance. In general populations, alkaptonuria is rare (1 in 250,000), but clusters of high incidence are found in certain groups with inbreeding (e.g., in Slovakia and Santo Domingo). Among Slovakian newborns the incidence is 1 in 19,000. Disease distribution is worldwide, and there is an approximately equal incidence in both sexes.[50]

Etiology and Pathogenesis

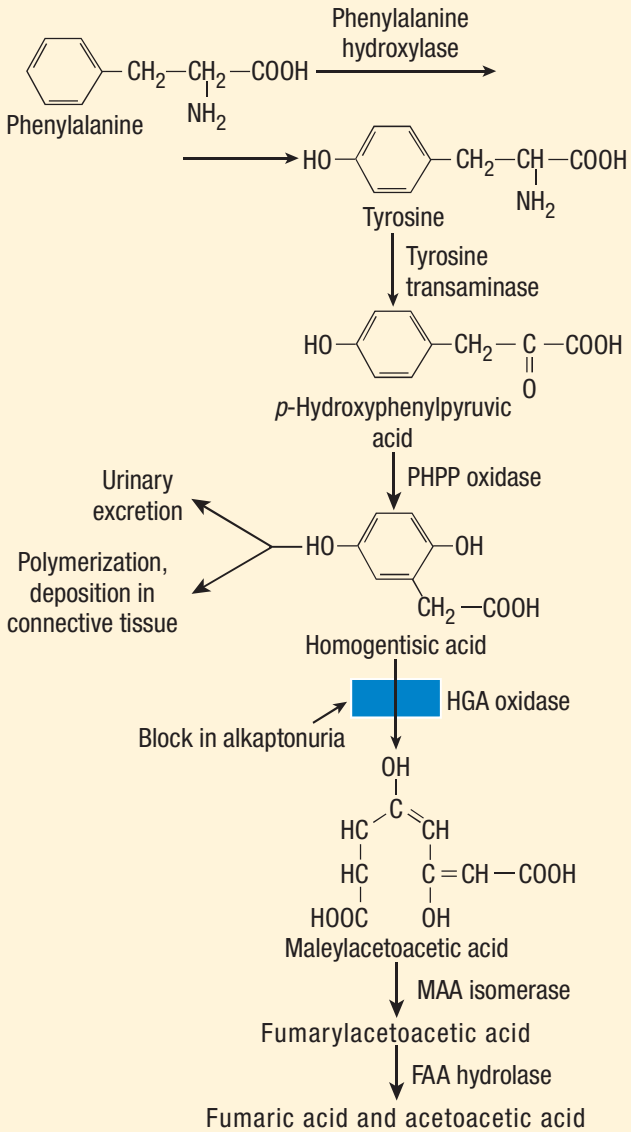
The *HGO* gene maps to the q21-q23.60 region of chromosome 3. Multiple mutations have been found.[51–53] The muta-

ALKAPTONURIA AT A GLANCE

- Autosomal recessive metabolic disease in which homogentisic acid, an intermediate product in the metabolism of phenylalanine and tyrosine, cannot be further metabolized (Online Mendelian Inheritance in Man #203500). The cause is a mutation in the homogentisate 1,2-dioxygenase acid oxidase gene on chromosome bands 3q21-q23.
- Clinical features are blue-black or gray discoloration of sclerae, face, pinnae, cartilage, and nails; dark sweat; arthritis; and homogentisic aciduria. Urine is dark after standing in alkaline pH.
- It is suggested that high tissue concentrations of ascorbic acid might delay and possibly reduce the degree of pathologic changes in the connective tissue.
- Differential diagnosis includes argyria, chrysiasis, and pigmentation after treatment with amiodarone and other medications.
- Prenatal diagnosis is possible through DNA analysis.

tions change residues, which are conserved evolutionarily between *Aspergillus* HGO and human HGO, which suggests that they are fundamental to the activity of HGO. Both compound heterozygotes and homozygotes have been detected.[54]

The biochemical pathway by which phenylalanine and tyrosine normally undergo oxidative degradation to acetoacetic acid is shown in Fig. 131-3. HGA (2,5-dihydroxyphenylacetic acid), the last molecule in the sequence to contain an intact aromatic ring, is cleaved to maleylacetoacetic acid (Fig. 131-5). The enzyme catalyzing ring cleavage, HGO, is normally present in the soluble fraction of liver and kidney cells. It is highly specific for HGA. HGO mRNA is found in liver, kidney, and prostate.[54] Atmospheric oxygen, ferrous ion, and sulfhydryl groups are required for enzymatic function. Quinones inhibit the enzyme. HGO activity is totally absent in both liver and kidney tissue from alkaptonuric subjects. In patients with alkaptonuria, HGA undergoes renal excretion or is transformed to



▲ **FIGURE 131-5** Metabolic pathway of phenylalanine and tyrosine degradation with homogentisic acid metabolites. FAA = fumarylacetoacetic acid; HGA = homogentisic acid; MAA = maleylacetoacetic acid; PHPP = *p*-hydroxyphenylpyruvic.

ochronotic pigment within connective tissue. HGA may not be present in the first days of life due to the absence of enzymatic activity of other enzymes in the pathway of tyrosine catabolism.

The renal clearance of HGA is extremely high (up to 400 to 500 mL/minute) in both normal and alkaptonuric subjects, which indicates active tubular secretion of HGA. This explains how with relatively low fasting plasma concentrations of HGA (in the range of 3 mg/dL) excretion may be up to 4 to 8 g/day in HGO deficiency. Compounds inhibiting this secretion may be an important factor in ochronosis. Once excreted, HGA (which is itself colorless in solution) gradually oxidizes to dark products. Oxidation occurs by degrees when the urine is exposed to air, but it can be hastened markedly by alkalinization. Urinary pH is the major variable causing the darkening of the urine, and some patients with acidic urine may never have spontaneously black urine. A diet high in protein or tyrosine increases the amount of HGA excreted in disease.

The precise manner by which HGA accumulation in tissues leads to ochronosis is only partially understood. A presumed HGA polymer has never been characterized.

Alkaptonuric mice (*aku*) do not have black urine or deposition of pigment, which is possibly related to the mouse's ability to synthesize ascorbic acid.[56]

Experimental ochronosis induced by prolonged feeding of high-tyrosine diets

to rats may delineate the precise interaction between HGA and its products and connective tissue.[57] HGO also has been produced in experimental animals by L-phenylalanine feeding and diets deficient in sulfur amino acids or tryptophan and the iron chelator α,α′-dipyridyl.

HGA inhibits lysyl hydroxylase, an enzyme crucial for collagen cross-linking, in chick embryo calvaria, which suggests that a reduction in the structural integrity of collagen consequent to deficient hydroxylysine-derived cross-linkages may be responsible for cartilaginous degeneration in alkaptonuria.[58]

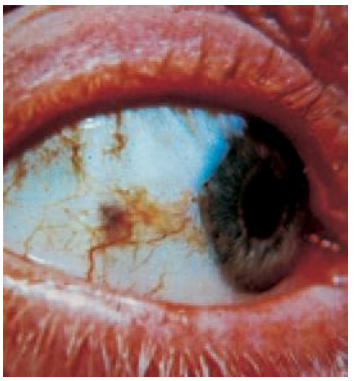
Clinical Features

Dark urine is not always the initial manifestation of HGO deficiency. The urine is most apt to discolor rapidly when pH is above 7.0 and when reducing substances such as ascorbic acid, which normally protect HGA from oxidation, are not present in sufficient quantity. An early diagnosis of HGO deficiency is frequently made when (1) it is specifically sought because of family history, (2) discoloration of diapers occurs after cleansing in (alkaline) soap, (3) the urinary pH favors the oxidation of HGA, or (4) testing for urinary glucose with Benedict's solution yields an orange precipitate (which indicates a reducing substance) accompanied by a dark supernatant. A positive finding for Benedict's reaction and a negative result on glucose analysis with a glucose oxidase test reagent strongly suggest the diagnosis.

Although the diagnosis of alkaptonuria may be made during childhood, in rare cases the disorder is not detected until the individual develops pathologically significant changes in connective tissue in the third or fourth decade.[59] If coincidental renal disease prevents effective HGA excretion, the development of ochronosis may be accelerated, and diffuse hyperpigmentation may result.

Dark brown or black cerumen may be present in the first decade, even in those younger than 5 years of age. Axillary skin pigmentation (greenish blue, blue, greenish yellow, or brown) in the pattern of glandular orifices may be present late in the first decade. This may be accompanied by staining of underwear ("sweat that stains"). A patient with pigmentary changes confined to sun-exposed areas has been described.[60]

A grayish blue tinge overlying ear cartilage is common in adulthood but is rarely seen before 20 years of age.[61] Ochronotic discoloration is rarely seen



▲ **FIGURE 131-6** Ochronosis (alkaptonuria) has pathognomonic ocular signs. The first to appear is grayish black scleral pigmentation anterior to the tendon insertions of the horizontal recti muscles. At times, pigmentation of the elastic tissue in pinguecula may stain a dark brown or black, and it usually has the configuration of small, dark rings. In advanced cases of ochronosis, Bowman's membrane, adjacent to the limbus, may have areas of black pigmentation.

in childhood but is common in adulthood and can affect the sclera, cornea, conjunctiva, tarsus, and eyelid skin. Scleral involvement is noted in most patients[62,63] (Fig. 131-6). Scleral discoloration generally is restricted to that portion of the globe exposed by the palpebral fissure. The scleral pigmentation is usually triangular, with the base of the triangle facing the cornea. Tiny "oil droplets" of ochronotic pigment appear at the inner and outer poles of the corneas in advanced ochronosis. Later in the disease, structural changes result in loss of transillumination, stiffening, irregular contours, and eventually, in the third decade, calcification of the pinnae. The tympanic membrane may be blue. Tinnitus and variable degrees of deafness have been ascribed to ochronotic degeneration of the tympanic membrane and underlying ossicles. Laryngeal and tracheal cartilage becomes heavily pigmented but is asymptomatic.

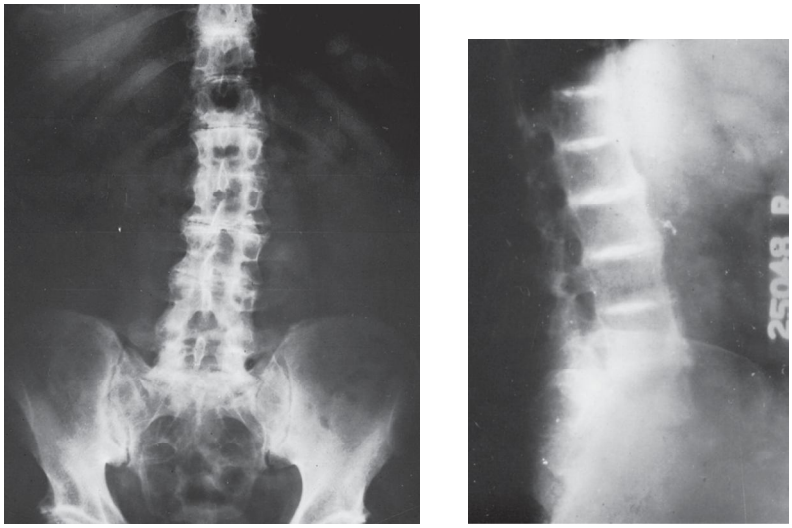
The visible changes that occur with the passage of time are primarily due to the formation of ochronotic pigment granules in the dermis and sweat follicles and, most important, to the transmission of ochronotic discoloration through thin areas of skin overlying pigmented cartilage and tendon. The latter pigmentation, which is fairly uniform in ochronosis, is most apparent at the nose tip, ear (Fig. 131-7), costochondral junctions, and extensor tendons of the hands. Pigmented colloid milium on the dorsa of the hands have been reported.[64] Pigmentation of the skin is less

▲ **FIGURE 131-7** Ochronotic discoloration seen through the thin area of skin overlying the pigmented cartilage of the ear.

prominent but may occur in a butterfly pattern on the nose and cheeks and even the palms as a presenting sign.[65] Rarely, bluish gray fingernails and intensely dark nevi have been reported. Exogenous ochronosis and striae atrophicae may follow the use of bleaching creams.[66]

Insidious progression of ochronotic arthropathy, which generally begins in the third and fourth decades in men and approximately 10 years later in women, is the most disabling manifestation of alkaptonuria.[67] The disease is more severe in males. Bouts of acute inflammation may occur. Hip, knee, and shoulder limitation is an early sign. Lumbar pain, lordosis, kyphosis, and sciatica are common. Radiographs show a characteristic appearance of early calcification of the intervertebral disk and later narrowing of the intervertebral spaces, with eventual disk collapse and progressive loss of height (Fig. 131-8). The hands and feet generally are spared. Pseudogout may coexist with ochronosis.

There is some suggestion of an increased incidence of cardiovascular disease in patients with ochronosis, but accelerated arteriosclerosis has not been clearly documented. At postmortem examination, pigmentation is commonly observed in the heart valves and annuli and in arteriosclerotic plaques.[68] Prostatic symptoms in older men frequently are due to the formation of soft pigmented calculi in the alkaline secretions of the ducts and sinuses of that gland. Porous black renal stones containing calcium, phosphate, and oxalate also have been reported. The prostate has high levels of HGO mRNA, which may ex-



▲ **FIGURE 131-8** Roentgenographic findings in ochronosis. Marked intervertebral disk calcification is present.

plain the black prostate calculi that are occasionally present in the disease.[41]

Laboratory Findings

Aside from the excretion of HGA, alkaptonuric patients show no abnormalities on routine clinical laboratory tests. Normal individuals do not excrete HGA; therefore, darkening of the urine on the addition of sodium hydroxide is presumptive evidence of alkaptonuria.

Other tests based on the reducing properties of HGA include the black reaction after treatment with $FeCl_3$ and blackening of photographic emulsion paper on application of a drop of alkaptonuric urine followed by a drop of sodium hydroxide. Specific identification and quantification of urinary (as well as blood) HGA can be achieved by the use of a direct spectrophotometric method using HGO or with high-performance liquid chromatography or stable isotopes.[54]

With the development of ochronotic arthropathy, radiographs of the spine show characteristic disk calcification, which occurs rarely in other forms of spondylitis (see Fig. 131-8). Periostitis, ligament calcification, and sacroiliac sclerosis are not features of ochronotic spondylitis.

PATHOLOGY Yellow to light-brown (ochre) pigment granules, which led to the original designation of *ochronosis*, are present as free bodies and in dermal macrophages.[69] Irregular masses may be over 100 μm in diameter. The pigment, in contrast to melanin, is not bleached by 10 percent H_2O_2 after 72 hours.[69] Routine special stains for melanin react with the ochronotic pigment.

Electron microscopic studies show smaller-sized homogeneous bodies fusing to form larger non–membrane-bound structures.[69] Although the original pigment is brown, Tyndall scattering of light makes involved skin appear blue.

The tendency of connective tissue, cartilage in particular, to darken gradually over the years constitutes the cardinal pathologic finding in alkaptonuria. Intervertebral disks are pigmented (jet black) and darken when examined. Articular cartilage, when heavily pigmented, displays the degenerative changes of fibrillation, fissuring, fragmentation, and erosion to bare bone. Phagocytosis of collagen fibrils is found in synovial macrophages.[70]

Diagnosis and Differential Diagnosis

The diagnosis of alkaptonuria may be made on the basis of typical urinary discoloration or may await the onset of ochronosis in adulthood. Inasmuch as the disease behaves in a quite stereotypical manner with few confusing variants in its mode of presentation, it has been concluded that the diagnosis need only be thought of to be made. Other causes of dark urine—melaninuria, porphyria, myoglobinuria, bilirubinuria, and hematuria—should not to be confused with alkaptonuria. An ochronosis-like pigmentation of skin and cartilage has been produced iatrogenically by quinacrine administration over a period of months and at the site of quinine injections.[69] Pigmentation due to antimalarial treatment is usually much more pronounced on mucosal surfaces and will fluoresce with a Wood's lamp. A slate gray to blue pigmentation in sun-exposed sites occurs after amiodarone treatment, and similar discoloration also involving the mucous membranes is seen in argyria and chrysiasis (Box 131-5).

Box 131-5

Differential Diagnosis of Alkaptonuria

Main Features

- Skin
  - Black-gray skin on ear cartilage.
- Eyes
  - Brown to black pigmentation of the sclera
- Rheumatologic features
  - Skeletal pathologies, including spinal degeneration with kyphosis
  - Ochronotic arthritis and arthropathy
  - Thickened Achilles tendon
- Miscellaneous
  - Urolithiasis
  - Ochronotic prostate stones
  - Aortic and mitral valve calcification

Consider

- Exogenous ochronosis
- Argyria
- Chrysiasis
- Treatment-induced pigmentation (amiodarone, quinacrine, quinine)

It is possible that the reversible ochronotic pigmentation caused by prolonged carbolic acid treatment is due to polymerization of the carbolic acid by HGA polyphenol oxidase to an HGA polymer–like substance that differs from the polymer found in the genetic disease by the reversibility of the polymerization.

Exogenous ochronosis and pigmented colloid milia have been reported in a number of South Africans who used hydroquinone bleaching creams at strengths greater than 2 percent for a prolonged period.[66,71,72] Forty-two percent of women and 15 percent of men who used hydroquinones developed exogenous ochronosis.[72] A similar condition has been seen in American blacks.[73]

Treatment

The course of alkaptonuria is generally slow but irreversible. Treatment is primarily supportive, with close observation for the development of arthropathy, cardiac disease, and urinary tract disease (Box 131-6). Appropriate management includes genetic counseling, pain management with nonsteroidal anti-inflammatory agents, physical therapy to increase range of motion, and

Box 131-6

Treatment of Alkaptonuria

- Avoidance of high-protein diet
- Avoidance of high-phenylalanine diet
- Avoidance of high-tyrosine diet
- Large amounts of dietary vitamin C
- 2(-2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione

regular follow-up visits.[20] Avoidance of high-protein, high-phenylalanine, and high-tyrosine diets has been reported to be important. A well-balanced normal diet seems the best approach during childhood. It has been postulated that large amounts of dietary vitamin C may be helpful, because vitamin C protects HGA against oxidation and thus may prevent the deposition of ochronotic pigment; however, no long-term clinical studies have been undertaken to verify the effectiveness of this approach.

It is disappointing that despite advances in our biochemical understanding of alkaptonuria and the disposition of accumulated HGA to form ochronotic pigment in connective tissue, this information has yet to be translated into a successful therapeutic program for managing the disease. Exogenous cutaneous ochronosis induced by hydroquinone has been treated with the carbon dioxide laser.[79]

Course and Prognosis

The ultimate course in adults with alkaptonuria is that of increasing pigmentation and skeletal incapacity. Little can be done to interrupt this progression; however, the disease is not incompatible with a normal life span, and the oldest patient on record lived to 99 years of age.

OTHER ABNORMALITIES OF AMINO ACID METABOLISM

Table 131-1 lists some of the abnormalities of amino and organic acid metabolism and their associated skin manifestations.

CHAPTER 132

The Porphyrias

David R. Bickers
Jorge Frank

The porphyrias are among the most intriguing diseases of humans. Widely variable, almost bizarre in their clinical manifestations, these disorders of porphyrin or porphyrin-precursor metabolism result from aberrations in the control of the heme biosynthetic pathway. Heme is essential for oxygen binding and transport (as in hemoglobin and myoglobin), for electron transport (as in cytochromes), and for the activity of mixed-function oxidases such as cytochrome P_{450}. Chlorophyll, a magnesium-chelated porphyrin, is another important tetrapyrrole that is critical for photosynthesis, the specialized energy-storing system found in plants in which the conversion of light energy into stabilized chemical energy is achieved with a sequence of oxidation-reduction reactions. The corrin ring, a cobalt-chelated tetrapyrrole, is a major constituent of vitamin B_{12}, the lack of which results in pernicious anemia. Porphyrins, therefore, are ubiquitous and essential biochemical constituents of living beings. The biologic importance of the porphyrins and their iron complexes in metabolism lies in their capacity to act as mediators of oxidation reactions, either as oxidative components in the metabolism of steroids, drugs, and environmental chemicals or as a means of exchanging gases, such as oxygen and carbon dioxide, between the environment and the tissues of the body.

Daily synthesis of porphyrins and heme in humans occurs in amounts suffi-

TABLE 132-1
Normal Values of Porphyrins and Porphyrin Precursors in Humans

Porphyrins or Precursors	Urine (μg/24 h)	Red Blood Cells (μg/100 mL Packed Cells)	Plasma (μg/100 mL)	Feces (μg/g Dry Weight)

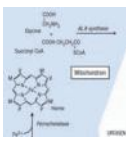
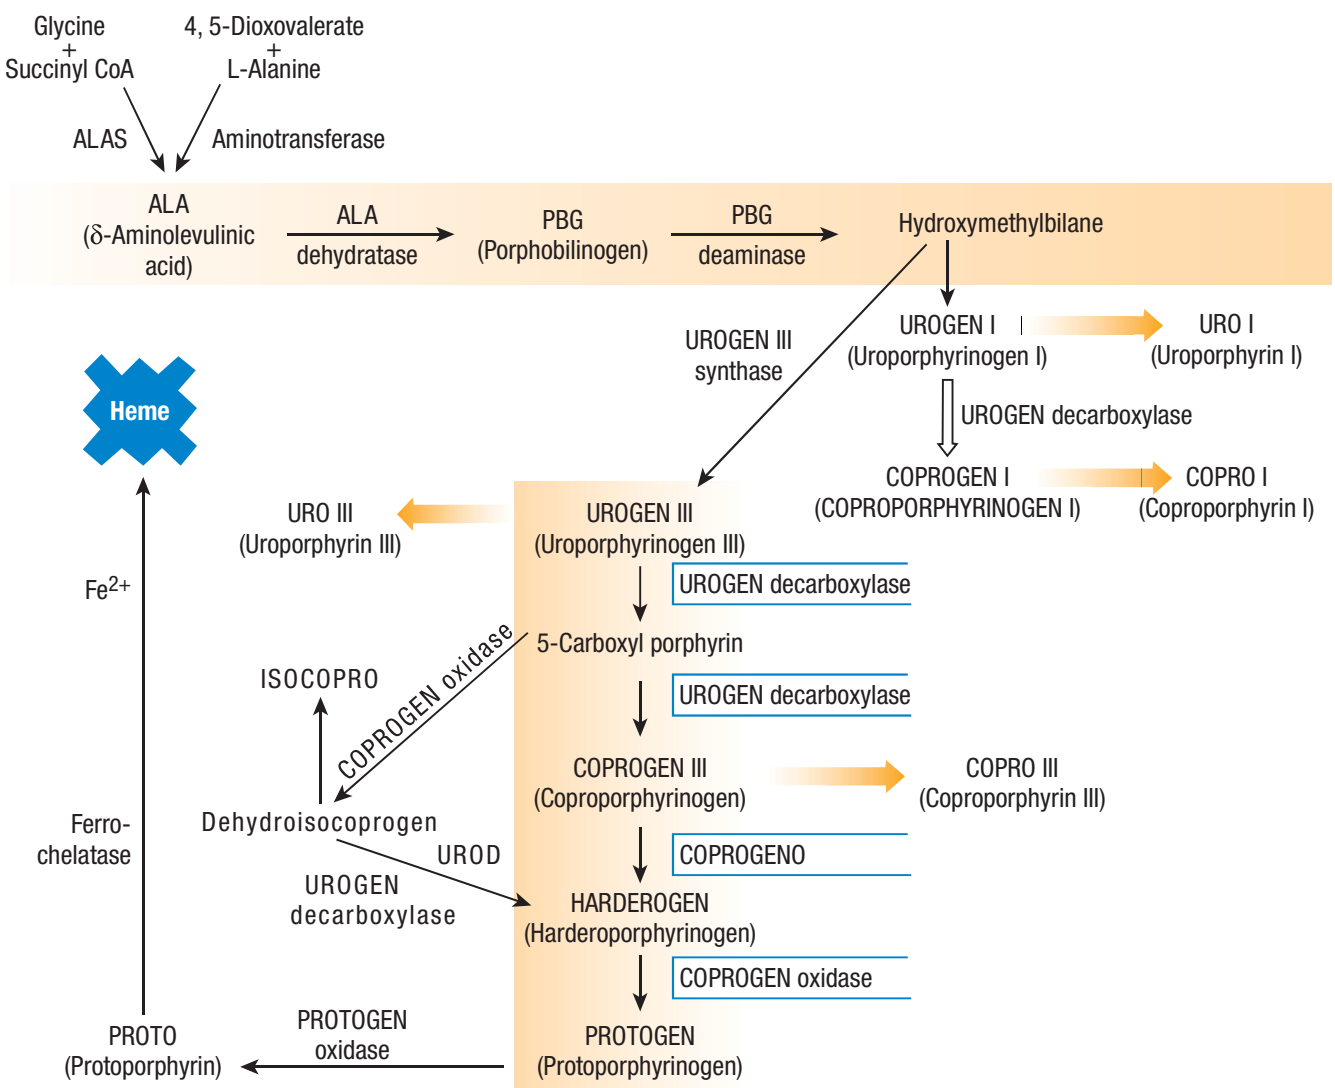
cient to provide for the body's metabolic requirements. The control of heme synthesis is so precise that, under normal circumstances, only microgram quantities or less of pathway intermediates are present in plasma, red blood cells (RBCs), urine, and stool (Table 132-1).

The porphyrias are a clinically and genetically heterogeneous group of metabolic diseases that result from either an inherited or an acquired dysfunction of enzymes crucial for heme biosynthesis (Fig. 132-1). Heme synthesis is controlled by eight enzymes along the heme biosynthetic pathway. The human porphyrias arise from deficient activity of the second to eighth enzymes in this pathway (see Fig. 132-1).[1–3] Each of these enzymes is discussed separately later in the context of the corresponding type of porphyria.

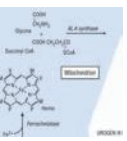
Biochemically, the different porphyrias are characterized by particular pat-





▲ **FIGURE 132-1** The porphyrin-heme biosynthetic pathway (see also legend for Fig. 132-2). ALAS = δ-aminolevulinic acid synthase; CoA = coenzyme A; COPROGENO = coproporphyrinogen oxidase; ISOCOPRO = isocoproporphyrin; UROD = uroporphyrin decarboxylase.

terns of accumulation and excretion of porphyrins and/or their precursors. In general, the porphyrins excreted in a specific type of porphyria are the irreversibly oxidized substrate(s) of the deficient enzyme (Table 132-2). These intermediates, when present in excess amounts, exert toxic effects that are responsible for the cutaneous and neurologic signs and symptoms of clinically overt porphyria. The porphyrias are of particular dermatologic interest because several types exhibit cutaneous manifestations that may permit diagnosis from clinical signs alone.



PORPHYRIN-HEME BIOSYNTHESIS

The major sites of heme synthesis in the body are the bone marrow and the liver. Heme is the prosthetic group for a number of proteins, including among others hemoglobin, myoglobin, mitochondrial cytochromes, microsomal cytochromes (including cytochrome P_{450}), catalase, peroxidase, tryptophan pyrrolase, prostaglandin endoperoxide synthase, and the soluble form of guanylate cyclase. Approximately 85 percent of heme synthesis occurs in the bone marrow, where heme is used for the production of hemoglobin; the majority of the rest occurs in the liver for production of cytochrome P_{450}, catalase, and various mitochondrial cytochromes. Heme is a critical cellular constituent essential for a variety of metabolic processes, primarily because of its unique ability to take up and release oxygen and to facilitate electron transport. Heme synthesis is regulated by the interplay of a number of factors and is directly dependent on its concentration within cells and on the requirements of the cell for production of the various hemoproteins listed at the beginning of the paragraph. Many of these have rapid turnover times (minutes to hours), which necessitates continuously high rates of hepatic heme synthesis (e.g., cytochrome P_{450}, an important membrane-bound enzyme in the liver involved in the detoxification and metabolism of drugs, has a half-life of 90 to 180 minutes).

Regulation of Heme Biosynthesis

The regulation of heme biosynthesis (and indeed the ability to synthesize heme at all) is dependent on the serial interaction of eight intracellular enzymes (see Fig. 132-1). The first, δ-aminolevulinic acid (ALA) synthase, and the last three enzymes involved, coproporphyrinogen (COPROGEN) oxidase, protoporphyrinogen (PROTOGEN) oxidase, and ferrochelatase, are mitochondrial, whereas the remaining enzymes, ALA dehydratase, porphobilinogen (PBG) deaminase, uroporphyrinogen III (UROGEN III) synthase, and UROGEN decarboxylase, are localized in the cytosol. Once heme is formed, heme cleavage is catalyzed by the microsomal enzymes nicotinamide adenine dinucleotide phosphate (reduced form)–cytochrome C reductase, heme oxygenase, and biliverdin reductase, which convert the cyclic tetrapyrrole to linear bile pigments. Complementary DNAs (cDNAs) for each of the eight enzymes involved in heme biosynthesis as well as the enzymes along the heme catabolic pathway have been cloned in mammalian cells.[2,3] Abnormal control of heme synthesis may result from defects in enzymes of the synthetic pathway, and this may occur as the result of inherited and/or environmental factors that lead to the accumulation in the body of one or more heme pathway intermediates, such as the porphyrins or their precursors. Although a diagnosis of porphyria can often be made from a careful medical history (including the familial history) and physical examination, the definitive diagnosis requires (1) measurement of porphyrins and/or porphyrin precursors in urine, stool, plasma, or erythrocytes (RBCs); or (2) measurement of the residual activity of specific enzymes in the heme pathway; or (3) the identification of mutations in the genes encoding these enzymes (see Fig. 132-1). Modern molecular biologic techniques have helped to clarify the mechanistic basis of the porphyrias.[3–8] The steps involved in the biosynthesis of porphyrins and heme and their regulatory control are summarized in Figs. 132-1, 132-2, 132-3, and 132-4.

TABLE 132-2
Enzyme Activities in Various Porphyrias

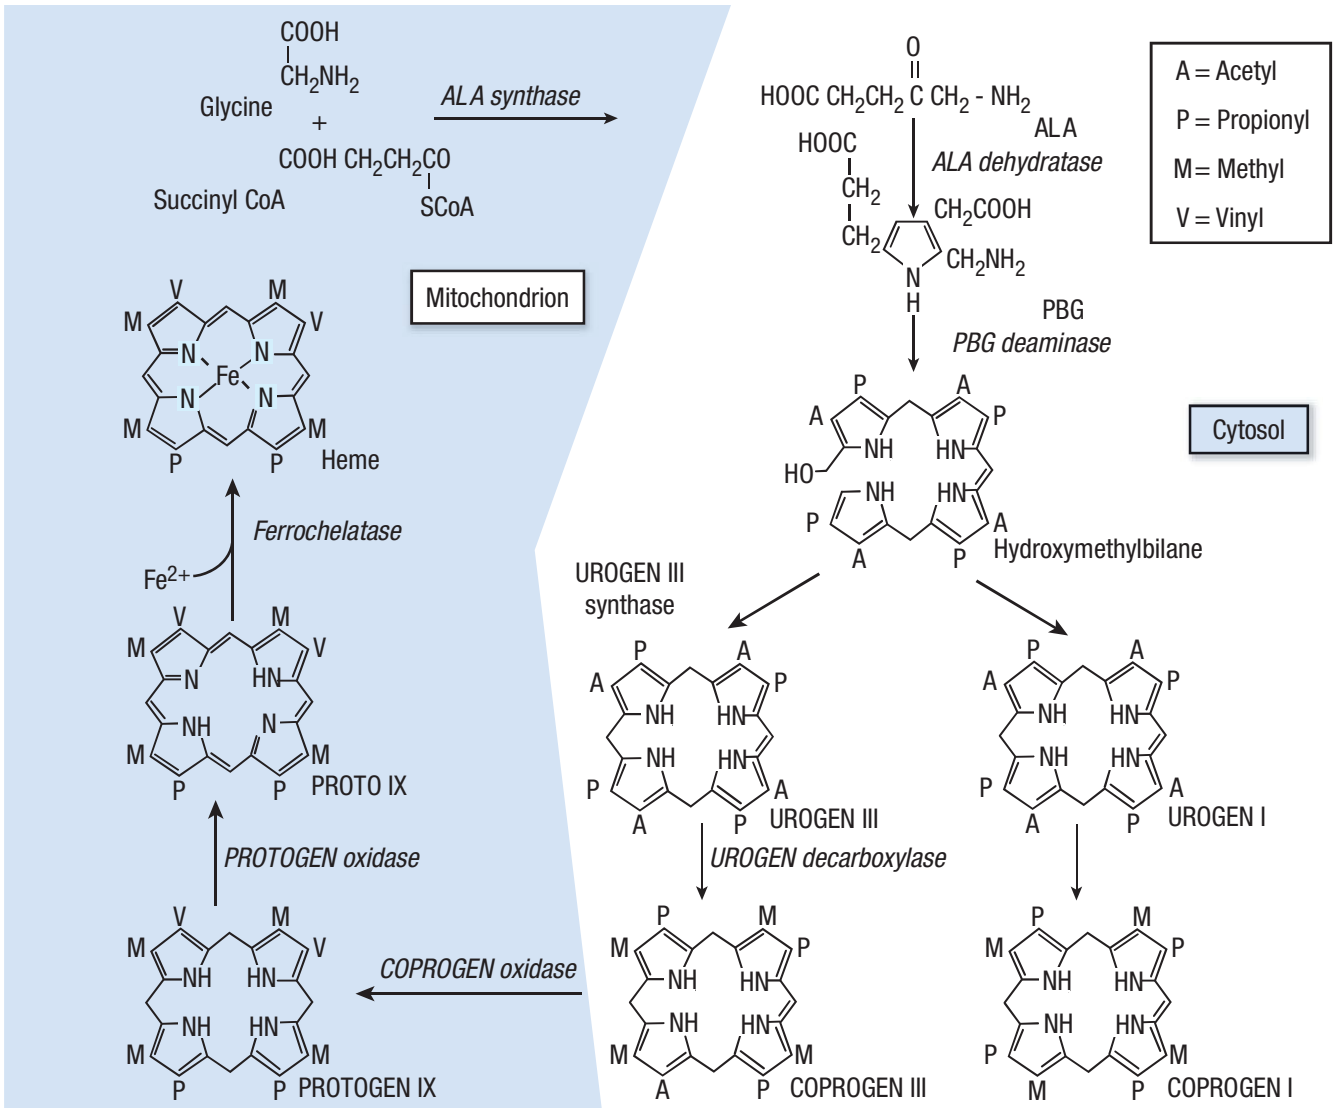
ENZYME	TISSUE	DISEASE-DISPLAYING ENZYMATIC DEFECT
δ-Aminolevulinic acid (ALA) synthase	Liver, kidney, fibroblasts, and lymphocytes	Increased activity in AIP, HCP, VP
ALA dehydratase	Erythrocytes, liver, and kidney	Decreased in lead intoxication, decreased in ALA dehydratase deficiency porphyria
Porphobilinogen deaminase	Erythrocytes, liver, fibroblasts, lymphocytes, and amnion cells	Decreased in AIP
Uroporphyrinogen III synthase	Erythrocytes and fibroblasts	Decreased in CEP
Uroporphyrinogen decarboxylase	Erythrocytes and liver	Decreased in PCT (sporadic and familial) and HEP
Coproporphyrinogen oxidase	Fibroblasts, lymphocytes, and liver	Decreased in HCP
Protoporphyrinogen oxidase	Liver and fibroblasts	Decreased in VP
Ferrochelatase	Bone marrow and fibroblasts	Decreased in EPP and lead poisoning

AIP = acute intermittent porphyria; CEP = congenital erythropoietic porphyria; EPP = erythropoietic protoporphyria; HCP = hereditary coproporphyria; HEP = hepatoerythropoietic porphyria; PCT = porphyria cutanea tarda; VP = variegate porphyria.

δ-Aminolevulinic Acid Synthase (See Figs. 132-1 and 132-2)

Heme synthesis begins in the mitochondrion of the cell where succinate and glycine (single molecules of glycine and succinyl coenzyme A) are conjugated to form a five-carbon aminoketone, ALA. The reaction requires pyridoxal 5′-phosphate as a co-factor. ALA synthase is the mitochondrial enzyme that catalyzes the formation of ALA and is a homodimer of two identical catalytically active subunits of molecular mass 55 kd, linked to catalytically inactive substrates of higher molecular mass.[3,8,9]

The major significance of this enzyme is that it plays a regulatory role in controlling the rate of heme synthesis in the liver via a negative feedback mechanism. Heme acts at multiple sites to regulate hepatic ALA synthase. Currently, two differentially expressed isoforms of ALA synthase are known, one with ubiquitous expression, including in the

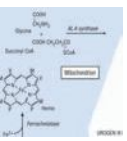


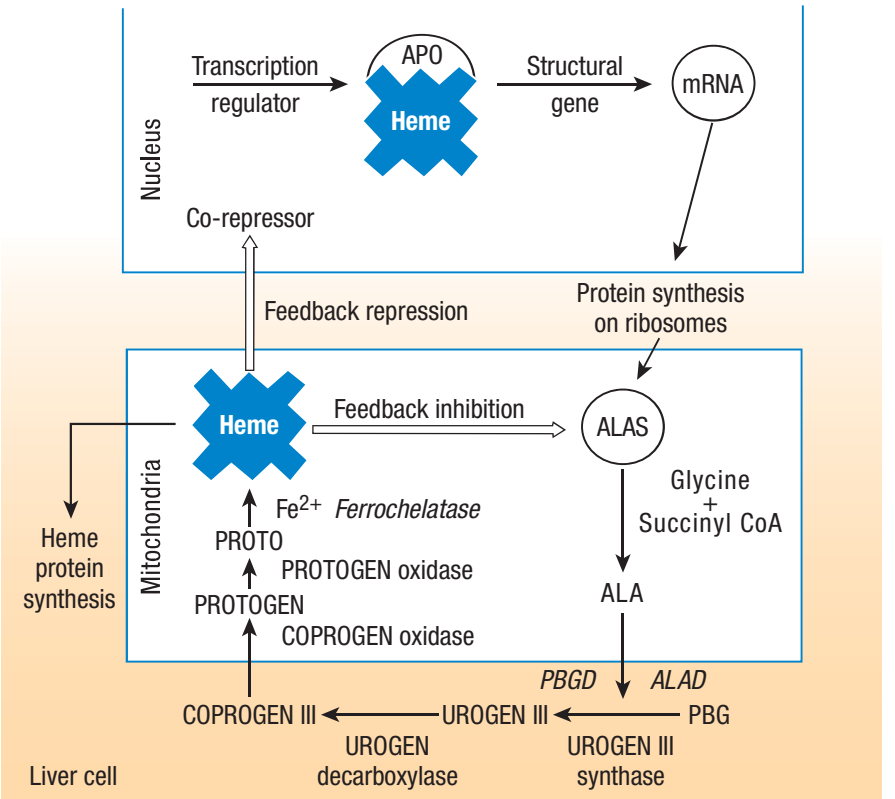
▲ **FIGURE 132-2** Major steps in the porphyrin-heme biosynthetic pathway. (1) δ-Aminolevulinic acid (ALA) synthase can be formed from glycine and succinyl coenzyme A (SCoA), which is the primary source in mammalian systems and is catalyzed by the mitochondrial enzyme ALA synthase. Two molecules of ALA form the monopyrrole porphobilinogen (PBG). (2) Four molecules of PBG are converted by PBG deaminase to a linear tetrapyrrole, hydroxymethylbilane, which can cyclize spontaneously to form uroporphyrinogen (UROGEN) I. (3) The four acetyl groups of UROGEN I are sequentially decarboxylated by UROGEN decarboxylase to form coproporphyrinogen (COPROGEN) I. (4) Hydroxymethylbilane can also be converted to UROGEN III by the enzyme UROGEN III synthase. In this reaction, one of the monopyrrole rings is "flipped over," which alters the sequence of the side chains. (5) The acetyl groups of UROGEN III are sequentially decarboxylated by UROGEN decarboxylase to form COPROGEN III. (6) COPROGEN III is converted to protoporphyrinogen (PROTOGEN) IX by the enzyme COPROGEN oxidase, which oxidatively decarboxylates each of the propionyl groups. (7) PROTOGEN IX is converted to protoporphyrin (PROTO) IX by PROTOGEN oxidase. PROTO IX is converted to heme by ferrochelatase, which catalyzes the insertion of ferrous iron into the molecule.

liver, and the other with exclusive expression in erythroid tissues. It is thought that two pools, one cytosolic and one nuclear, regulate the respective isozymes. Two genes encoding different tissue-specific ALA synthase messenger RNAs (mRNAs) have been found. The human housekeeping gene is located on chromosome 3p21, and the erythroid gene has been assigned to a distal subregion of chromosome Xp21-Xq21. The erythroid pre-protein reveals more than 75 percent homology with the hepatic protein. Immunochemical differences exist between the hepatic and erythroid enzyme in various animal species.[9,10] In contrast to deficiencies of the second to eighth enzymes in the heme biosynthetic pathway, a reduction in residual ALA synthase activity is not associated with a specific type of porphyria.

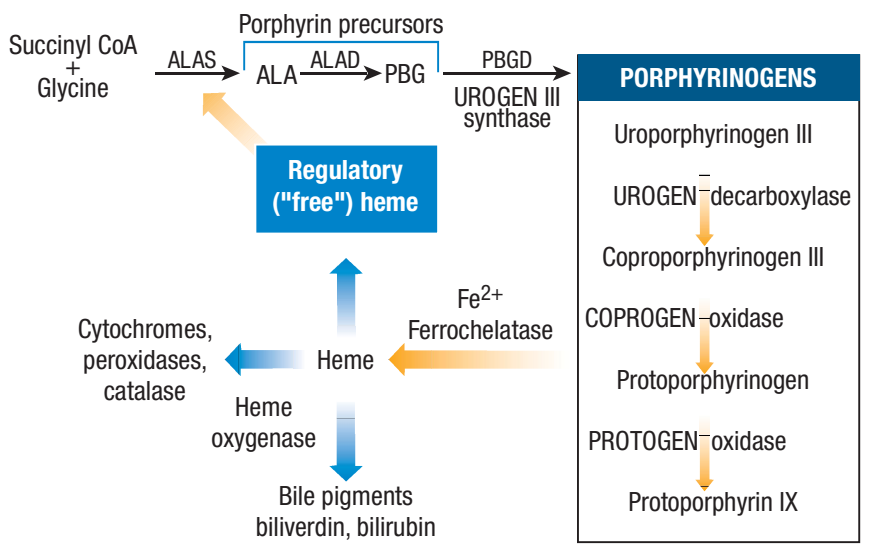
CLASSIFICATION OF THE PORPHYRIAS

Traditionally, most classifications of the porphyrias are based on the primary site of expression of the specific enzymatic defect, so that erythropoietic and hepatic forms are distinguished. From a dermatologic perspective, the porphyrias might also be classified into cutaneous and non-cutaneous forms. From a general clinical perspective, however, it seems reasonable to classify the porphyrias into two categories, non-acute and acute, so that patients in whom dermatologic findings predominate are differentiated from those who are susceptible to potentially life-threatening acute neurovisceral attacks. This latter classification is used throughout this chapter. It should be pointed out that variegate porphyria (VP) and hereditary coproporphyria (HCP) are often referred to as *neurocu-*





▲ **FIGURE 132-3** Heme is capable of regulating its synthesis by either directly inhibiting or repressing the synthesis of its rate-limiting enzyme, δ-aminolevulinic acid synthase (ALAS). The repression may result from the binding of heme, as a co-repressor, to an aporepressor protein (APO), which, when combined with heme, becomes a functional unit that blocks transcription of ALAS messenger RNA (mRNA). Heme may also block transport of the holoenzyme into the mitochondrion. ALA = δ-aminolevulinic acid; ALAD = δ-aminolevulinic acid dehydratase; CoA = coenzyme A; COPROGEN = coproporphyrinogen; PBGD = porphobilinogen deaminase; PROTO = protoporphyrin; PROTOGEN = protoporphyrinogen; UROGEN = uroporphyrinogen.



▲ **FIGURE 132-4** A regulatory pool of "free" heme unbound to apoproteins may be the critical determinant for regulation of synthesis of δ-aminolevulinic acid synthase (ALAS) activity. THE PORPHYRIAS AT A GLANCE

- The porphyrias result from a dysfunction of specific enzymes involved in heme biosynthesis.
- At least eight different types of porphyria are known and can be classified as nonacute and acute.
- Cutaneous features manifest exclusively on sun-exposed body areas.
- Life-threatening acute neurologic attacks can occur.
- Diagnosis is often difficult due to overlapping clinical and biochemical findings.
- All genes encoding the enzymes involved in heme synthesis are well characterized, which allows for accurate molecular diagnosis and genetic counseling.

taneous porphyrias because patients with these diseases may have both neurovisceral and cutaneous manifestations.

An acute porphyric attack can present a constellation of symptoms and signs, among them intense abdominal pain, vomiting, electrolyte dysregulation (hyponatremia), constipation, tachycardia, hypertension, muscle pain and weakness, seizures, paresis of the upper and lower extremities, paralysis, and a variety of other neurologic and psychiatric symptoms.[11] These myriad clinical manifestations inevitably mimic those of other diseases, which challenges the diagnostic acumen of even the most experienced clinicians, particularly because the porphyrias are rare disorders.[12] It is known that acute porphyric attacks can be precipitated by a variety of external factors, in particular porphyrinogenic drugs, ethanol, hormonal fluctuations, and diminished caloric intake from dieting or fasting.[11,13] Yet in practice it is often impossible to identify the immediate cause of an acute crisis in an individual patient. Timely diagnosis of an acute porphyric attack can be lifesaving, because several complications may have fatal consequences if not recognized and treated. As an example, in a patient with episodic abdominal pain, treatment with analgesics may prolong or aggravate the

attack. Diffuse abdominal pain can mimic acute appendicitis, diverticulitis, or other painful gastroenterologic disorders that may necessitate surgical intervention.[14,15] After administration of certain drugs (e.g., barbiturates) or during general anesthesia, acute attacks may ensue.[1] A particularly problematic complication is muscle weakness. This can range from mild paralysis of small muscle groups to flaccid paralysis of multiple muscle groups resulting in paraplegia and respiratory compromise. These findings may be accompanied by severe sensory loss and amyotrophy.[16] In some cases, paralysis may progress rapidly and can affect cranial nerves or develop into a Guillain-Barré–like syndrome.[17]

NON-ACUTE AND ACUTE PORPHYRIAS

Patients with all forms of non-acute porphyria manifest cutaneous findings predominantly on sun-exposed body areas. The non-acute porphyrias include porphyria cutanea tarda (PCT), the most prevalent type of porphyria overall; erythropoietic protoporphyria (EPP); congenital erythropoietic porphyria (CEP); and hepatoerythropoietic porphyria (HEP), the homozygous variant of PCT. The non-acute porphyrias can present with variable cutaneous features, including mild to severe photosensitivity, increased skin fragility, vesicles and bullae, burning and stinging, edema, pruritus, hypertrichosis, scarring, hyperpigmentation, and mild to severe scleroderma-like changes.[4]

The acute porphyrias include acute intermittent porphyria (AIP), VP, HCP, and ALA dehydratase deficiency porphyria or plumboporphyria. Although AIP is the most prevalent form of acute porphyria worldwide, in some countries other acute forms may predominate, as is the case for VP in Chile and South Africa.[18,19] Besides neurovisceral symptoms, individuals with VP or HCP can also present with cutaneous findings, including increased photosensitivity, abnormal skin fragility, and bullous skin lesions on sun-exposed areas, erosions, chronic scarring, and post-inflammatory pigmentary change. Thus, VP and HCP are also referred to as *neurocutaneous porphyrias*, to distinguish them from AIP and ALA dehydratase deficiency porphyria, which are not associated with any cutaneous abnormalities.[4,20]

It is of interest that ethanol and estrogens, which can trigger acute porphyric attacks in AIP, VP, and HCP, can also exacerbate PCT, although acute attacks do not occur in this disease and the mechanisms likely differ.[21]

Pathophysiology of Cutaneous Signs and Symptoms in the Non-Acute Porphyrias

The most common cutaneous manifestation of the non-acute porphyrias is photosensitivity. It is observed in patients with several of these disorders (PCT, EPP, CEP, HEP) as well as in patients with VP and HCP, who have both cutaneous and neurovisceral findings. The sine qua non of photosensitivity in porphyria is increased levels of plasma and tissue porphyrins. Patients with AIP, in whom only non-photosensitizing porphyrin precursors (ALA, PBG) are formed in substantially increased amounts, do not experience photosensitivity, nor do any of the handful of patients reported with ALA dehydratase deficiency porphyria.

Patients with the erythropoietic types of porphyria frequently complain of a painful and intense burning sensation and pruritus during or after sun exposure. A "priming" effect of sun exposure on cutaneous photosensitivity in EPP has been described in which a threshold exposure on one day that evokes virtually no reaction seems to augment the response to subsequent exposure on the following day.[22] The cause of this is unknown, but the phenomenon suggests that repair of damage to skin by photosensitized porphyrins may be prolonged. These subjective symptoms are notably absent in patients with the chronic hepatic porphyrias such as PCT and VP. Although there is some information about the pathophysiology of photosensitivity and sclerodermoid skin changes in the chronic hepatic porphyrias, the causes of the pigmentary alterations and hypertrichosis seen in these patients remain to be elucidated.

Porphyrins have certain unique photobiologic and spectroscopic properties that make them efficient photosensitizers. It is important to note that metal-chelated porphyrins [e.g., heme or ferrous protoporphyrin (PROTO)] show no fluorescence and are not photosensitizers. Porphyrins that are chelated to other paramagnetic metals, such as Mn^{2+}, Co^{2+}, or Zn^{2+} (e.g., chlorophyll, zinc PROTO), also do not fluoresce. For this reason, patients with lead intoxication, in which zinc PROTO level is elevated, do not have photosensitivity.[23,24] However, metal-free porphyrins [e.g., uroporphyrin (URO), coproporphyrin (COPRO), PROTO] in acidic solutions show a major absorption peak in the 400- to 410-nm region (Soret band); they also exhibit four additional absorption bands with decreasing intensity between 500 and 700 nm. Exposure of porphyrins to the Soret band spectra results in fluorescence emission peaks between 550 and 680 nm (Table 132-3). Although there is no single clearly defined pathway that can currently explain the photosensitization evoked by porphyrins and light, there are a number of potential cellular and soluble factors that likely are involved. Among them are reactive oxygen species (ROS) and their effect on certain cells (erythrocytes, mast cells, polymorphonuclear cells, and fibroblasts), and soluble mediators (the complement system and matrix metalloproteinases), which are discussed later in the section Cellular and Soluble Factors Contributing to Photosensitivity (Table 132-4). It is likely that a combination of these factors will prove to be responsible for the pathogenesis of the cutaneous lesions in the porphyrias.

Of note, porphyrin abnormalities can also occur in lead poisoning; sideroblas-

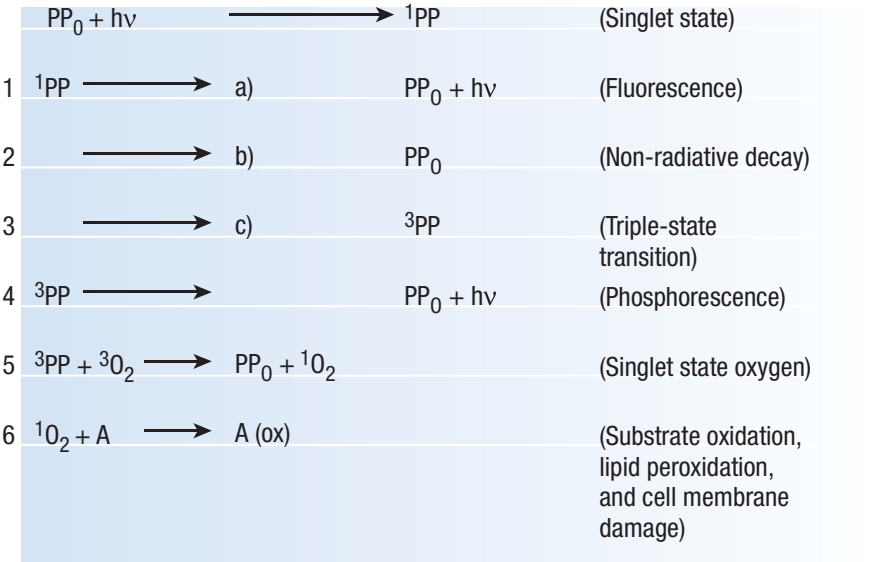
tic, hemolytic, and iron deficiency anemia; renal failure; cholestasis; liver disease; and gastrointestinal hemorrhage. Of these conditions, however, cutaneous photosensitivity has been documented only in rare cases of sideroblastic anemia.

Pathophysiology of Neurovisceral Signs and Symptoms in the Acute Porphyrias

Two porphyria variants, AIP and ALA dehydratase deficiency porphyria, do not manifest cutaneous symptoms. In these diseases, the dysfunctional enzymes act early in heme biosynthesis, and their substrates are non-phototoxic porphyrin precursors. However, patients with both AIP and ALA dehydratase deficiency porphyria as well as VP and HCP can manifest life-threatening acute neurovisceral attacks. Although the exact pathogenesis of these attacks is not well understood, it seems that the porphyrin precursors ALA and PBG that are massively excreted from the liver during an acute attack are particularly neurotoxic. Furthermore, as a result of porphyria-related enzyme defects, there may be heme deficiency in nerve tissue. Thus, the autonomic and peripheral nervous systems are particularly susceptible to porphyrin- and porphyrin precursor–induced neuropathy.[25]

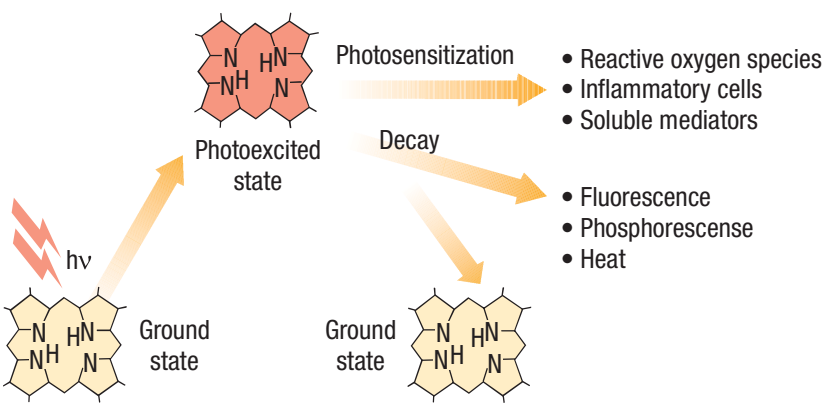
Cellular and Soluble Factors Contributing to Photosensitivity (See Table 132-4)

REACTIVE OXYGEN SPECIES Porphyrins such as URO, COPRO, and PROTO absorb light intensely around 400 nm and in the longer visible spectrum between 580 and 650 nm. Absorption results in the generation of excited state porphyrin molecules (Fig. 132-5). The initial excited state porphyrin generated has an extremely short half-life of less than 0.01 μs. Singlet excited state porphyrins may spontaneously convert to a triplet, another excited state that has a lower energy level but a longer half-life (on the order of microseconds to milliseconds). Because of their long half-life, triplet state porphyrins are more likely to react with biologic substrates and are likely candidates to mediate most porphyrin-associated photobiologic reactions. Excited state porphyrin molecules ultimately must return to their normal ground states by releasing their absorbed energy in the form of light (fluorescence is emitted by singlet state molecules and phosphorescence by triplet state molecules) or heat, or by transferring energy to cell constituents (cell membranes, organelles, proteins, DNA) (see Figs. 132-5 and 132-6).

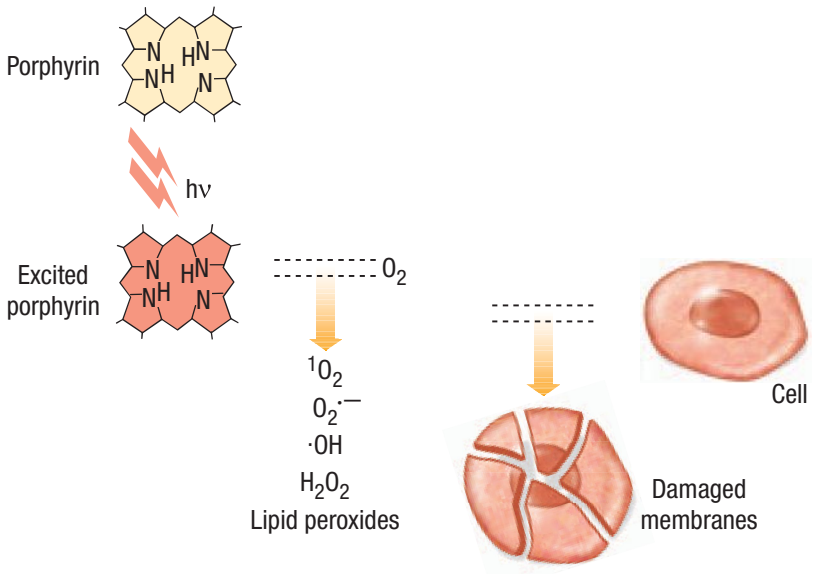


▲ **FIGURE 132-5** Photoexcited porphyrins release energy in a variety of ways when returning to their ground state, and these may contribute to damaging reactions in biologic systems. A = acceptor; A (ox) = oxidized acceptor; hν = radiant energy; PP = photoexcited porphyrin.

Excited porphyrins in their singlet and triplet states can also transfer their absorbed energy to oxygen molecules, thereby creating reactive excited oxygen states.[26] Cellular and tissue damage induced by photoactivated porphyrins is believed to occur primarily as a result of the formation of reactive singlet oxygen ($^1O_2$), as illustrated in Figs. 132-5 and 132-7.[27,28] In some cases, the sensitized porphyrin may further react with oxygen to yield hydrogen peroxide (H_2O_2) or with water to form hydroxyl radicals



▲ **FIGURE 132-6** Porphyrins in a ground state, on absorption of radiant energy (hν), undergo transition to photoexcited states. The photoexcited porphyrins generate reactive oxygen species, which damage cells by release of pro-inflammatory mediators; in turn, these may contribute to damaging reactions in biologic systems such as skin.



▲ **FIGURE 132-7** Photoexcited porphyrins in their triplet state transfer the absorbed energy to oxygen (O_2) molecules, thereby producing reactive oxygen species ($^1O_2$, $O_2^{\cdot-}$, ·OH, and lipid peroxides). These reactive oxygen species interact with cell membranes to cause tissue damage. hν = radiant energy.

(OH). Those processes in which activated oxygen species play a role in photosensitization are referred to as *photodynamic reactions*.[29] Most of the porphyrin-mediated cutaneous photosensitization reactions are essentially photodynamic and can be minimized or prevented if reactive oxygen is eliminated by inactivation processes known as *quenching* or *scavenging*.

Although these concepts regarding excited porphyrins and ROS are valid in simple systems and several hypotheses based on them have been advanced to explain the mechanism of porphyrin-induced photosensitivity, their applicability to complex tissues such as the skin remains to be established.

COMPLEMENT SYSTEM Cutaneous phototoxicity in the porphyrias is directly related to the interaction of porphyrins with light of the Soret and other bands in the solar spectrum, which results in the generation of ROS. This in turn can induce lipid peroxidation and cell membrane alterations. Release of mediators and enzymes from cells such as mast cells and polymorphonuclear leukocytes contributes to the inflammatory response. Variations in solubility influenced by the lipid-water partitioning of porphyrins may account for the striking patterns of the skin findings observed in various types of porphyria. It is important to emphasize that porphyrinogens (reduced porphyrins) are the true intermediates in heme synthesis. The irreversibly oxidized porphyrins, with the exception of PROTO, do not function as substrates for the enzymes of the pathway. Thus, porphyrins are actually heme pathway by-products, which are of special interest to dermatologists because of their unique photosensitizing properties.

THE NON-ACUTE PORPHYRIAS (Table 132-5)

Porphyria Cutanea Tarda

EPIDEMIOLOGY PCT occurs throughout the world[46] and is the most common of all the porphyrias. The prevalence is estimated at 1 in 10,000.[47] The disease most often begins in middle-aged individuals but can develop earlier. Before the widespread use of oral contraceptives, PCT developed predominantly in males.[48,49] Others, however, have emphasized that the sex incidence is now approximately equal.[50] The rising incidence of PCT in females is probably due to the widespread ingestion of estrogens in oral contraceptives or in hormone supplements. It should be noted that males treated with estrogens, for example as adjunctive therapy for carcinoma of the prostate, have also developed PCT.

ETIOLOGY AND PATHOGENESIS PCT is due to either an inherited or an acquired de-

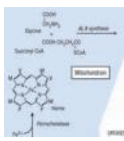


TABLE 132-5
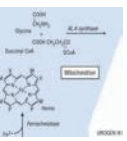
Overview and Summary of the Features of the Non-Acute Porphyrias

	Porphyria Cutanea Tarda	Erythropoietic Protoporphyria	Congenital Erythropoietic Porphyria	Hepatoerythropoietic Porphyria
Synonym(s)	Symptomatic porphyria, acquired hepatic porphyria, chemical porphyria	Erythropoietic porphyria, protoporphyria	Günther disease, congenital hematoporphyria, erythropoietic uroporphyria	Hepatoerythrocytic porphyria
Inheritance	Autosomal dominant in approximately 20% of patients; otherwise acquired	Autosomal dominant	Autosomal recessive	Autosomal recessive
Age of onset	Usually in third or fourth decade; rare before puberty	Early childhood (1–4 yr); late onset extremely rare	Usually infancy or first decade	Early infancy, before age 2 yr
Incidence	Most common porphyria worldwide	Second most common of the cutaneous porphyrias	Very rare (fewer than 200 cases)	Extremely rare (fewer than 20 cases)
Photosensitivity	Moderate to severe with high interindividual variation; indistinguishable from variegate porphyria	Mild to severe; onset immediate (in minutes); interindividual variation	Severe to very severe	Severe
Skin reactions (on sun-exposed areas)	Vesicles and bullae, erosions, crusts, milia, scarring, hypertrichosis; indistinguishable from variegate porphyria	Edema, erythema, urticarial plaques; very rarely bullae, skin thickening, waxy scars	Vesicles and bullae, erosions, hypertrichosis, hypermelanosis, mutilation	Vesicles and bullae, erosions, crusts, milia, scarring, hypertrichosis, mutilation

PORPHYRIA CUTANEA TARDA AT A GLANCE

- Most frequently occurring type of porphyria worldwide.
- Sporadic and inherited (autosomal dominant) forms of the disease arise due to deficiency of uroporphyrinogen decarboxylase.
- Age of onset is usually in the third to fourth decade of life; the disorder is unusual before puberty.
- Characterized by moderate to severe photosensitivity; cutaneous signs include vesicles and bullae, erosions, crusts, milia, scarring, hyperpigmentation, and hypertrichosis.
- Cutaneous features overlap with those of variegate porphyria and hereditary coproporphyria.



ficiency of UROGEN decarboxylase, the fifth enzyme in the heme pathway (see Figs. 132-1 and 132-2), which has a molecular mass of approximately 42 kd.[51] UROGEN I and III each contain eight carboxyl groups as side chains, four of which are acetate ($-CH_2COOH$) and four of which are propionate ($-CH_2-CH_2-COOH$) moieties (see Fig. 132-2). The soluble cytosolic enzyme UROGEN decarboxylase catalyzes the sequential oxidative decarboxylation of the four carboxyl groups of the acetate side chains to methyl groups to form COPROGEN (see Fig. 132-2). Decarboxylation first occurs on ring D, after which the enzyme turns around to decarboxylate rings A, B, and C in a clockwise fashion. This converts the original 8-carboxyl porphyrinogen (UROGEN I or III) first to 7-carboxyl, then to 6-carboxyl and to 5-carboxyl porphyrinogen. The 5-carboxyl porphyrinogen can then undergo decarboxylation of its last acetyl group to form the 4-carboxyl porphyrinogen that is known as *COPROGEN I* or *III* (see Fig. 132-2). These intermediates are also referred to as *hepta-*, *hexa-*, *penta-*, and *tetracarboxylate porphyrinogens*. COPROGEN I cannot be further metabolized to heme.

Human UROGEN decarboxylase is encoded by a single-copy gene of the same name, *UROGEN decarboxylase*, that is located on chromosome 1p34, spreads over a genomic distance of 3 kilobases (kb), and contains 10 exons.[51] The human UROGEN decarboxylase cDNA has been isolated, and the deduced sequence was found to be equivalent to 367 amino acids, consistent with the molecular mass and the amino acid composition of the purified protein.

Most classifications of PCT separate the disorder into at least two broad categories, both associated with decreased UROGEN decarboxylase activity: (1) acquired PCT, also referred to as *sporadic* or *type I PCT*; and (2) hereditary PCT, also referred to as *familial* or *type II PCT*.

In acquired (type I) PCT, the enzyme is deficient only in the liver, which could be explained either by the presence of a different gene defect restricted to the liver or by exposure to chemicals that selectively inhibit the hepatic but not the RBC enzyme.[52] Some of these substances (e.g., alcohol and estrogen) may provoke PCT only in selected individuals and others (e.g., hexachlorobenzene or HCB) in practically all exposed individuals.

Hereditary (type II) PCT is an autosomal dominant disorder, and the residual UROGEN decarboxylase activity is decreased approximately 50 percent in all tissues, including RBCs and cultured skin fibroblasts.[53–56] Decreased enzyme concentration appears to follow a bimodal distribution, which suggests two overlapping groups of patients: A large group (more than 80 percent) with normal UROGEN decarboxylase concentration and a small group (fewer than 20 percent) in whom the amount of detectable enzyme is about half the normal level. Some patients with type II PCT were found to have UROGEN decarboxylase activity at the lower end of the normal range. The clinical penetrance of type II PCT is relatively low (approximately 20 percent), so that the majority of individuals with the inherited enzyme defect do not manifest the disease. This suggests that additional genetic or non-genetic factors are needed for disease expression. To date, more than 100 different mutations in the *UROGEN decarboxylase* gene have been identified that either decrease the stability of the enzyme or produce defective pre-mRNA splicing.[3,47,51,56–59]

It is important to emphasize that not every patient with a positive family history of PCT will have type II disease. In support of this notion, several patients have been described who have one or more relatives with PCT but have normal RBC UROGEN decarboxylase activity.[60] This latter category of PCT has been designated as type III by some investigators.[54] Either these patients could have inherited some form of UROGEN decarboxylase that is immunochemically indistinguishable from the normal enzyme but that is uniquely susceptible to inhibition in the liver, or they could have a second inherited enzyme deficiency unrelated to UROGEN decarboxylase. These possibilities require further investigation.

It is likely that some patients who were initially reported as having hereditary PCT actually had VP, another dominantly inherited porphyria. PCT and VP may occur in different members of the same family in the so-called *dual porphyrias*.[61–63] Another form of dual porphyria in which PCT and AIP co-exist has also been described.[64]

Numerous agents and conditions are known to contribute to the development of PCT (type I, acquired, or sporadic), including alcohol; estrogens; iron; viral infections [hepatitis C and human immunodeficiency virus (HIV) infection]; polychlorinated hydrocarbons, particularly HCB and 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD); and hemodialysis in patients with renal failure (Table 132-6). Each of these precipitating factors is discussed briefly in the following sections.

Alcohol. Alcohol ingestion has long been recognized to exacerbate PCT. Ethanol has been shown to induce hepatic ALA synthase in patients with PCT.[65] Erythrocyte UROGEN decarboxylase activity is diminished in healthy individuals after acute ethanol ingestion and in those with chronic alcoholism.[66] Ethanol can also inhibit the activity of other enzymes in the heme pathway, including ferrochelatase and

TABLE 132-6
Drugs and Chemicals Associated with the Clinical Expression of Porphyria Cutanea Tarda

- Ethyl alcohol
- Estrogenic hormones
- Hexachlorobenzene (HCB)
- Chlorinated phenols
- Iron
- 2,3,7,8-Tetrachlorodibenzo-*p*-dioxin (TCDD)
- Polychlorinated biphenyls (PCB)
- Herbicides 2,4-dichloro- and trichlorophenoxyacetic acid

ALA dehydratase. Chronic alcoholism leads to suppression of erythropoiesis[67] and increased absorption of dietary iron, which are perhaps linked to inherited mutations associated with hemochromatosis (see Iron). The fact that ALA synthase is increased in patients with hepatic cirrhosis without porphyria raises questions concerning the relevance of alcohol effects on ALA synthase in the clinical expression of PCT.[68]

Estrogens. The widespread use of estrogens as contraceptive agents or as hormone supplements for post-menopausal hormone replacement therapy in females and as adjunctive hormonal therapy in males with prostatic carcinoma has been associated with the development of PCT.[50] The mechanism of the estrogen effect on the expression of PCT has not been elucidated. Although diethylstilbestrol, an estrogen, induces hepatic ALA synthase,[69] this would not explain the distinctive porphyrin excretion pattern found in PCT. The vast majority of patients receiving estrogens do not manifest the biochemical abnormalities associated with PCT.

Hexachlorobenzene. The fungicide HCB caused an "epidemic" of a PCT-like syndrome in southeastern Turkey in the 1950s.[70] It was added as a preservative to wheat intended for planting, but because of a famine, several thousand individuals of diverse ethnic origin, mostly children, ingested the seed wheat and subsequently developed typical PCT. Over 4000 cases of this syndrome were reported between 1956 and 1961. The porphyrin excretion pattern and the cutaneous findings in these patients were quite similar to those seen in PCT evoked by ethanol or estrogens. The outbreak of PCT in Turkey caused by ingestion of HCB indicated that the disease could occur in non–genetically predisposed individuals.

Twenty-five years later, the most common clinical findings in these HCB-poisoned individuals were those of chronic porphyria, including sclerodermoid scarring (84 percent), hyperpigmentation (78 percent), hirsutism (49 percent), thyromegaly, and increased skin fragility (38 percent).[71] A painless arthritis was seen in two-thirds of affected individuals, and a variety of neurologic signs and symptoms occurred in the majority. Stool and urine porphyrin levels remained elevated in many patients.

Studies have shown that the long-term administration of HCB to experimental animals produces excessive porphyrin accumulation in the liver in a pattern quite similar to that seen in PCT in humans.[72] These data are consistent with the hypothesis that chlorinated hydrocarbons such as HCB, or their metabolites, inhibit hepatic UROGEN decarboxylase, which leads to excessive hepatic storage of URO and other acetate-substituted porphyrins.[73,74] Experimental studies have also shown that HCB can inactivate UROGEN decarboxylase and thereby abolish catalytic activity without changing the amount of immunoreactive enzyme protein.[75] Chemical porphyria similar to PCT is caused by other chlorinated hydrocarbons such as the polychlorinated biphenyls and TCDD, a by-product in the synthesis of the herbicide 2,4,5-trichlorophenoxyacetic acid.[76] Additional studies on the porphyrinogenic effects of chlorinated hydrocarbons suggest that metabolic activation of the compounds mediated by cytochrome P_{450} 1A2 and involving iron-generated ROS is associated with an attack on the catalytic site of UROGEN decarboxylase.[56,77]

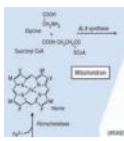
Tetrachlorodibenzo-p-Dioxin. TCDD is a toxic environmental pollutant. Among its numerous effects are chloracne, liver damage, and hepatic porphyria in experimental animals and perhaps also in humans.[78] It has been shown that the hepatic porphyrinogenic effect of TCDD can be abolished in mice by first depleting them of iron.[79] Furthermore, it is known that highly inbred mouse strains vary in their susceptibility to induction of hepatic porphyria by TCDD, which indicates that the porphyrogenic effect of this hydrocarbon is modulated by as yet undefined genetic factors.[80]

Iron. Serum iron and ferritin concentrations are elevated or in the upper range of normal in individuals with PCT, which confirms the important role of iron in the pathogenesis of the disease.[81] Hepatic iron overload accompanies clinical PCT in practically all cases, and elevation of plasma iron level is found in one-third to one-half of patients.[50] In PCT, the quantity of iron that can be mobilized by phlebotomy indicates that total iron stores are approximately twice the normal level. Ferrokinetic studies in patients with PCT are said to yield normal results. The long remissions that follow repeated phlebotomy and the apparent ineffectiveness of this treatment if supplemental iron is administered concomitantly suggest that iron plays a role in the excessive hepatic porphyrin production in PCT.[82] PCT is particularly common when alcoholism and iron overload occur together.

The role of iron in the pathogenesis of PCT is complex, and several hypotheses have been proposed to explain it. Iron may directly inhibit UROGEN decarboxylase. However, studies using purified UROGEN decarboxylase prepared from human erythrocytes show that the purified enzyme is not inhibited by Fe^{2+} or Fe^{3+} ions.[83] Chronic iron overload can produce peroxidative damage to lipid-rich mitochondrial and microsomal membranes in the liver of experimental animals, but the relationship of this toxic effect to changes in hepatic heme synthesis has not been clearly defined.[84] An increased frequency of the hemochromatosis C282Y mutation in a gene encoding for a human leukocyte antigen class I–like protein, *HFE*, has been found in British patients with sporadic PCT.[85,86] This mutation is responsible for much of the iron overload in populations of European descent. A second mutation in the *HFE* gene, H63D, may also be associated with PCT in some populations.[87] PCT is rare in heterozygotes for each of these mutations, but 20 percent of British patients with PCT are C282Y homozygotes. C282Y homozygosity is an important susceptibility factor for both type I and type II PCT.[57]

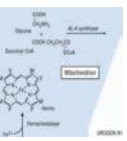
Iron may have a permissive effect on the inhibition of UROGEN decarboxylase by halogenated hydrocarbons, and it can also enhance the induction response of hepatic ALA synthase to drugs.[88,89] Although such an iron-augmented increase in ALA synthase activity could lead to enhanced porphyrinogenesis, this alone would not explain the porphyrin excretion pattern seen in PCT. Kushner, Lee, and Nacht have shown that the addition of ferrous iron to liver in vitro causes a marked increase in porphyrin synthesis and inhibits UROGEN III synthase activity, which provides an explanation for the URO isomer I excess that is characteristic of PCT.[90] More recently, a mouse model of type II PCT was developed in which one allele of UROGEN decarboxylase is disrupted, and these animals were then bred to mice homozygous for HFE disruption.[91] These animals developed a PCT-like phenotype.

Viral Infections. There is an association between PCT and hepatitis C virus (HCV) infections and combined HCV and HIV infections.[92,93] The role of these viruses in the pathogenesis of PCT



is unclear, although some connection with the *HFE* gene mutation H63D has been suggested.[56] It is also possible that the connection is fortuitous and secondary to non-specific hepatotoxic effects of these viruses.

From these known effects of alcohol, estrogens, chlorinated hydrocarbons, iron, and viral infections on the heme pathway, it is clear that each of these could contribute to the excessive hepatic porphyrinogenesis characteristic of PCT. There is growing evidence that hepatic siderosis is the critical pathologic endpoint in PCT and that the other agents somehow intensify the ability of iron to attack the catalytic site of UROGEN decarboxylase. The clinical expression of PCT is therefore dependent on the interaction of a number of factors, both genetic and environmental. However, it is important to note that the ingestion of drugs that have been associated with the induction of acute neurovisceral attacks in the acute porphyrias is not known to exacerbate similar neurologic crises in PCT.

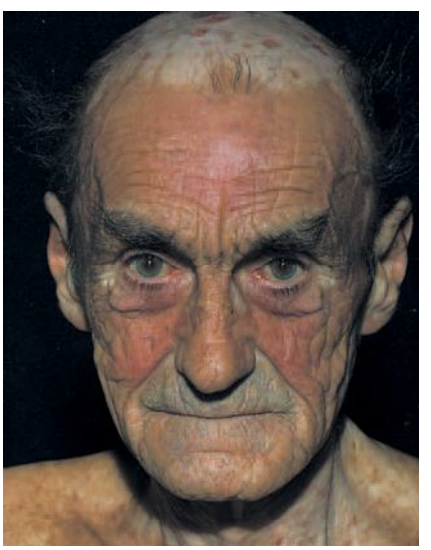


CLINICAL MANIFESTATIONS Vesicles and bullae followed by erosions and crusting occur predominantly in areas subject to repeated trauma (Fig. 132-8). There is increased skin fragility, usually on the dorsa of the hands. The traumatized skin becomes crusted, and as the lesions resolve, areas of scarring may ensue. Numerous small milia can develop, particularly on the fingers and hands. These are pearly white to yellow in each of the hepatic porphyrias associated with cutaneous photosensitivity (PCT, VP, and HCP) (see Fig. 132-8). Although the cutaneous lesions are seen primarily on the light-exposed areas, patients are often unaware that sunlight plays a role in producing their lesions, because the acute painful and burning photosensitivity so characteristic of the erythropoietic porphyrias is rare in PCT. However, most patients do recognize that their skin condition worsens in the spring and summer and seems to improve in the fall and winter. Porphyrin excretion in PCT appears to increase in the summer months and decrease in the winter months.

Other skin changes seen in PCT include hyperpigmentation and hypopigmentation that may be mottled, resembling chloasma. There may be an associated purplish red ("heliotrope") suffusion of the central part of the face, particularly involving the periorbital areas, which may bear a striking resemblance to the plethora seen in polycythemia rubra vera (Fig. 132-9). This is not seen in the porphyrias of bone marrow origin.

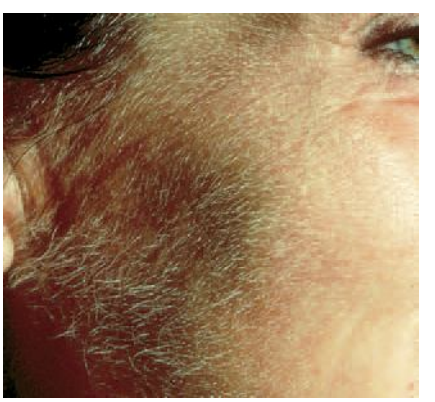
▲ **FIGURE 132-8** A case of porphyria cutanea tarda showing bullae filled with clear fluid. Elsewhere are remnants of blisters and on the second metacarpophalangeal joint are small milia.

Hypertrichosis (non-virilizing) is a useful diagnostic sign that often brings the female patient to the dermatologist (Fig. 132-10). Facial hypertrichosis develops gradually and is more apparent in females. The hair may vary in texture from fine to coarse and in color from light to dark. These hairs are particularly prominent along the temples and the cheeks but may occasionally involve the trunk and extremities in severe cases. Such hair may continue to grow, darken, and thicken, particularly on the cheeks, the forehead between the eyes, and at the hairline of the scalp. Males may complain that shaving is more difficult and that the growth pattern of their beard has changed. Hypertrichosis may be the presenting symptom in women, and a particularly severe form of hypertrichosis may occur in younger children with PCT and HEP. In the reports of HCB poisoning in Turkey, some of the children were described as "monkey-like" because of marked hypertrichosis.[94] The mechanism of this phenomenon is unknown; androgen levels are reported to be normal. It is possible that surface receptors or growth factors for hair bulb keratinocytes are activated by the dual action of light and porphyrins. The hypertrichosis of PCT usually improves slowly after depletion of excessive hepatic iron stores.



▲ **FIGURE 132-9** Porphyria cutanea tarda. Purple-red suffusion ("heliotrope") of central facial skin is most pronounced in the periorbital and frontal areas. Note also sclerodermoid plaque on scalp.

Sclerodermoid plaques can occur in PCT and in HEP and typically develop on both light-exposed and light-protected body areas (see Fig. 132-9; Fig. 132-11).



▲ **FIGURE 132-10** Hypertrichosis in a female with porphyria cutanea tarda; mostly pronounced on the zygomatic and malar skin.

▲ **FIGURE 132-11** Shiny sclerodermoid plaques on the chest of a patient with porphyria cutanea tarda.

These are usually scattered, waxy yellow to white, indurated plaques that closely resemble morphea or scleroderma both clinically and histopathologically. There is some evidence to indicate that PCT may occur concomitantly with true scleroderma, but this seems to be quite rare. URO I stimulates collagen synthesis in human skin fibroblasts.[37] In some patients, calcification has developed in these sclerodermoid plaques, which necessitates excision and grafting.

PCT-like syndromes are occasionally seen in association with hepatic tumors and lupus erythematosus.[95,96] Sub-epidermal bullous dermatoses mimicking PCT clinically and histologically have been described (see Pseudoporphyria). A number of cases of true PCT have occurred in patients with renal failure undergoing hemodialysis.[97] Confirmation of the diagnosis rests on detection of markedly elevated plasma levels of porphyrins (usually 5- to 100-fold) and increased levels of isocoproporphyrin (ISOCOPRO) in the feces (Table 132-7).

LABORATORY FINDINGS Patients with PCT excrete increased amounts of porphyrins in the urine, which rarely may exhibit characteristic pink-red fluorescence when examined with a Wood's lamp. The porphyrin excretion pattern of PCT has three main features: (1) increased urinary excretion of URO and of other acetate-substituted porphyrins; (2) a distinctive pattern of excretion of isomer series I and III porphyrins; and (3) increased excretion of fecal ISOCOPRO.[56,98,99] PCT patients excrete greatly increased amounts of urinary 8-carboxyl URO and also porphyrins with 7, 6-, and 5-carboxyl groups; the level of 4-carboxyl porphyrin (COPRO) is also increased but to a lesser extent than that of URO and rarely surpasses 600 μg per 24 hours (see Table 132-7). In PCT, the hepatic UROGEN decarboxylase deficiency results in the accumulation of 5-carboxyl porphyrinogen III (see Figs. 132-1 and 132-2). This can be used as a substrate by the enzyme COPROGEN oxidase, thereby forming dehydroisocoproporphyrinogen, which in turn is oxidized to ISOCOPRO. This results in the characteristic elevation of this compound in the feces of these patients.

The 8-carboxyl URO and 7-carboxyl porphyrins are the predominant urinary porphyrins in patients with PCT (more than 90 percent of total porphyrins). The urinary porphyrin excretion pattern is a mixture of type I and type III isomers. URO is approximately 60 percent type I isomer and 40 percent type III; the 7- and 6-carboxyl porphyrins are more than 90 percent type III and less than 10 percent type I isomer; the 5- and 4-carboxyl porphyrins are approximately 50 percent each isomer. This distinctive isomer pattern is found consistently in patients with PCT.

In general, only trace amounts of URO are present in the stool of individuals without porphyria. The porphyrin content of stool is increased in patients with PCT and consists primarily of ISOCOPRO (type III), 7-carboxyl porphyrin, and lesser amounts of URO and COPRO. The total daily 24-hour fecal porphyrin excretion may exceed total urinary porphyrin excretion.

The ratio of URO to COPRO in the urine is often helpful in differentiating PCT and VP. In PCT, the URO-COPRO ratio is usually greater than 3:1, whereas in VP the ratio is usually less than 1:1. Occasionally, 24-hour urine porphyrin levels will be normal or only slightly increased in a patient with the cutaneous findings of PCT. This should alert the physician to evaluate stool porphyrins, because these are elevated in patients with VP (see Variegate Porphyria).

It should be emphasized that patients with clinical signs of PCT may have negative results on a urine fluorescent screening test for porphyrins. In such patients, it is absolutely essential to obtain plasma porphyrin levels and perform quantitative 24-hour urine URO and COPRO determinations and stool PROTO and COPRO determinations, preferably using high-performance liquid chromatography, which often permit differentiation of PCT from VP. Rarely, some patients with VP will have normal fecal porphyrin excretion, and bile porphyrin measurements may be helpful in evaluating such patients.[100]

Virtually all patients with PCT have excessive total body iron stores manifested as increased serum iron, ferritin, and/or hepatocellular iron levels. Occasionally, there is mild erythrocytosis. An abnormal glucose tolerance test result is seen in a minority of patients.

Biochemical tests for liver function may be performed to identify liver disease. Elevated serum transaminase and γ-glutamyltranspeptidase levels may be found. Serum iron and ferritin concentrations may be elevated. The measurement of erythrocyte UROGEN decarboxylase is useful for the detection of patients with type II PCT. Mutational analysis is an essential part of evaluating these patients (see Molecular Genetic Research Strategies for the Porphyrias).

HISTOPATHOLOGY The characteristic histopathologic finding in PCT is a sub-epidermal blister (Fig. 132-12). Bullae typically show a corrugated, undulating base that has been termed *festooned*.[101] There is little or no inflammatory infiltrate. Periodic acid-Schiff (PAS) stain reveals a mild degree of thickening of the papillary vessel wall, not nearly as marked as that seen in patients with EPP. Reticulin staining demonstrates slight proliferation of fibers along the basement membrane. Direct immunofluorescence studies reveal deposition of C3 and immunoglobulin G in a granular pattern at the dermal-epidermal junction and in and around vessel walls in affected individuals.[102] These changes are most apparent in sun-exposed areas in patients with active disease and high urinary porphyrin excretion, and they decrease substantially in patients after appropriate treatment. It is also possible that the deposition of immunoglobulins and complement is a non-specific result of injury to the cutaneous tissue. The injury seen to the upper dermal vessels and at the dermal-epidermal junction suggests that damage to these areas induced by porphyrin photosensitivity may be responsible for the unique skin fragility seen in PCT.

Regardless of these findings, it should be emphasized that histopathologic examination does not substantially contribute to confirming the diagnosis of PCT. This is also true for the other cuta-

neous porphyrias. Consequently, it is not essential to perform a skin biopsy if one of the cutaneous porphyrias is suspected, mainly for two reasons: First, simple non-invasive biochemical laboratory techniques (see Laboratory Tests earlier) can usually permit presumptive diagnosis of porphyria, and second, external trauma (such as a biopsy or excision) inevitably constitutes an avoidable risk for delayed and/or dysfunctional wound healing, which is a characteristic feature of all cutaneous porphyrias.

DIFFERENTIAL DIAGNOSIS Other dermatoses that can be confused with PCT include VP, HCP, mild forms of HEP and/or CEP, pseudoporphyria, scleroderma, and epidermolysis bullosa acquisita. Each of these can be differentiated by appropriate porphyrin studies. Careful evaluation of urine, stool, and plasma porphyrins will almost always permit confirmation of the diagnosis of PCT. Nonsteroidal anti-inflammatory drugs, such as naproxen, and antibiotics, such as the tetracyclines and nalidixic acid, as well as a variety of other agents, may rarely produce bullous lesions closely resembling PCT but in contrast to it show no evidence of abnormal porphyrins (see Pseudoporphyria).

TREATMENT (Box 132-1) Initially, a careful history should be taken in an effort to identify an environmental toxin (e.g., alcohol, estrogen, or chlorinated hydrocarbon) that may have triggered the disease. If HCV or HIV infection is present, these should be managed appropriately. Elimination of toxin exposure alone may result in gradual improvement. In most patients with PCT, however, more aggressive treatment is usually appropriate to accelerate therapeutic benefit, and this currently consists of either repeated phlebotomy[56,103,104] or orally administered antimalarials (either chloroquine or hydroxychloroquine),[105,106] or a combination of both.[107] Other forms of treatment that have been described include administration of iron chelators[108,109] and the oral administration of cholestyramine.[110]

Phlebotomy. Phlebotomy is still the treatment of choice for PCT. Numerous reports have emphasized the safety and efficacy of this form of therapy,[111] which was introduced by Ippen.[103] Phlebotomy is effective because it depletes the excessive hepatic iron stores characteristic of PCT. Biochemical remission of PCT has occurred in patients treated with phlebotomy with iron overload as well as in patients with quantitatively normal iron stores. Replenishment of iron after phlebotomy-induced remission of PCT has resulted in biochemical and clinical exacerbation of the disease. Abstinence from the environmental triggers alone, especially alcohol, may induce a clinical and biochemical remission, although this may take months to years.[111]

The efficacy of phlebotomy may relate to several effects:

1. *Iron effects on ALA synthase.* Iron can enhance the induction response of ALA synthase to drugs and the hepatic porphyrinogenic response to HCB in experimental animals, and its depletion could render ALA synthase less inducible and thereby diminish hepatic porphyrinogenesis.
2. *Iron depletion effects on other heme pathway enzymes.* Ferrous iron inhibits UROGEN decarboxylase and increases the rate of hepatic porphyrin synthesis from ALA or PBG, which suggests that removal of iron can allow UROGEN decarboxylase activity to return to normal and/or reduce excessive porphyrinogenesis.[81,90] This concept has been verified by the creation of genetically engineered mice

Box 132-1

Treatment of the Non-Acute Porphyrias

TYPE	MANAGEMENT
Porphyria cutanea tarda	☐ Photoprotection (e.g., with broad-band sunscreens and/or protective clothing) ☐ Avoidance of sun exposure and trauma ☐ Discontinuation of alcohol ingestion and estrogen therapy ☐ Phlebotomy (venesection): 400–500 mL every 2 wk over 3–6 mo ☐ Low-dose chloroquine treatment: 125 mg twice weekly for 6–12 mo until porphyrin excretion is within normal range ☐ Measurement of urinary porphyrin excretion and plasma porphyrins quarterly to monitor progress
Erythropoietic protoporphyria	☐ Photoprotection (e.g., with broad-band sunscreens and/or protective clothing) ☐ Avoidance of sunlight exposure (common window glass does not provide protection) ☐ Oral β-carotene: 30–90 mg/day in children; 60–180 mg/day in adults; desirable maximum plasma level is 600–800 μg/dL
Congenital erythropoietic porphyria	☐ Photoprotection (e.g., with broad-band sunscreens and/or protective clothing) ☐ Strict avoidance of sunlight exposure ☐ Change of day-night rhythm ☐ Splenectomy if hemolytic anemia is severe ☐ Bone marrow transplantation
Hepatoerythropoietic porphyria	☐ Photoprotection (e.g., with broad-band sunscreens and/or protective clothing) ☐ Strict avoidance of sunlight exposure and trauma ☐ Change in day-night rhythm ☐ *Caution:* Therapeutic approaches used in porphyria cutanea tarda (phlebotomy, antimalarials) are ineffective.

in which iron overload inhibits the enzyme.

3. *Iron effects on hepatic lipid peroxidation secondary to ROS.* Iron depletion could reverse this response of the liver to iron overload.[84]
4. *Iron effects on oxidation of URO.* Removal of iron could result in a diminished capacity of the ferrous metal to irreversibly oxidize the UROGEN substrate to non-metabolizable porphyrins.[112]

Phlebotomy is carried out as an ambulatory procedure. The total amount of blood removed varies widely, usually ranging from 1500 to 12,000 mL. It is most convenient to use plastic blood-drawing bags available in any blood bank. Approximately 500 mL of blood is removed at weekly or biweekly intervals until the hemoglobin level decreases to approximately 10 g/dL or until the serum iron level drops to 50 to 60 µg/dL. Some believe that phlebotomies should be continued until serum ferritin level falls to the lower range of normal. Patients are strongly encouraged to discontinue or decrease exposure to porphyrinogenic agents, because this usually hastens clinical and biochemical remission.

It is particularly important to reassure the patient that clinical improvement may not become apparent for variable intervals after the phlebotomies are begun. Porphyrin excretion continues to fall long after phlebotomies are discontinued. It has been shown that in more than 90 percent of patients treated with regular phlebotomy, urinary URO excretion reaches normal levels (less than 100 µg/24 hour) after 5 to 12 months.[111] Blistering is the first sign to disappear; this is followed by improvement in skin fragility and in hypertrichosis over a period of 3 to 18 months. Even sclerodermoid changes can resolve slowly, although this may take several years. There are few published data on long-term follow-up of treatment, but most patients who experience relapse have again responded to repeated courses of phlebotomy.[104] The length of remission induced by phlebotomy varies widely and ranges from 6 months to more than 10 years. At least 10 percent to 20 percent of patients will experience relapse within 1 year.

Phlebotomy is a safe, effective, and relatively simple form of therapy with minimum associated morbidity. A few patients may complain of mild to moderate fatigue and weakness during the treatment period, but this usually resolves as the hemoglobin level returns to normal.

Antimalarials. In some patients, phlebotomy is not recommended or is contraindicated because of the presence of anemia, cardiopulmonary disorders, or HIV infection. In such cases low-dose antimalarial therapy is a useful alternative. The antimalarial aminoquinolines chloroquine and hydroxychloroquine are used.[105,106] In 1957, it was first suggested that chloroquine was useful in treating PCT.[113] The cutaneous signs of the disease cleared within 1 year in one patient who received 500 mg daily for several months. Such dosages may trigger severe hepatotoxicity in many PCT patients, however, and this is no longer considered an acceptable approach.

Instead, low-dose chloroquine therapy at a dosage of 125 mg twice weekly is effective in treating PCT and avoids the hepatotoxic effects of high-dose therapy.[114] In addition to producing a successful therapeutic outcome in single patients and small cohorts,[115] low-dose chloroquine (125 mg twice weekly for 8 to 18 months) has been used successfully to treat more than 100 patients with PCT.[116] Liver function test results and urinary porphyrin levels are monitored quarterly, and the medication is continued until urinary URO level is less than 100 µg/24 hours. This usually requires 6 to 12 months of treatment. Studies comparing the therapeutic efficacy of phlebotomy with that of low-dose chloroquine suggest that they are equally efficacious, and, likewise, the clinical and biochemical remission of PCT obtained with chloroquine appears to be identical in all respects to that induced by phlebotomy. However, it has been reported that rapid relapse occurred in several patients treated with hydroxychloroquine,[117] and therefore chloroquine may be preferable. The mechanism of action of chloroquine may relate to the formation of water-soluble drug-porphyrin complexes that are then excreted from the liver.[118] Taljaard et al., however, believe that chloroquine chelates iron in the hepatocyte and that the bound iron is then eliminated.[115]

The combination of phlebotomy and chloroquine treatment may reduce the severity of the hepatotoxic response to chloroquine and also accelerate remission of the disease.[107] Patients are treated with a series of one to four phlebotomies before starting chloroquine therapy (250 mg daily for 7 days). The procedure is repeated when signs of biochemical or clinical relapse develop, which may occur in 1 to 2 years. It should be emphasized that despite the tendency of the antimalarials to evoke hepatotoxic responses in patients with PCT, there is no evidence to suggest that the changes in hepatocellular pathology characteristic of PCT worsen as a result of treatment with these drugs.[119] The antimalarials may cause retinopathy, and the low-dose regimen helps to minimize the risk of this complication. Pre-treatment and semi-annual ophthalmologic examinations should be performed in patients treated with these drugs. In patients with PCT and chronic renal failure, standard phlebotomy and antimalarial therapy are not feasible. The combination of high-dose recombinant erythropoietin and small-volume phlebotomy has been successful in selected patients.[120]

HEPATO-ERYTHROPOIETIC PORPHYRIA AT A GLANCE

- Extremely rare (approximately 25 cases reported).
- Autosomal recessive disorder due to homozygous deficiency of uroporphyrinogen decarboxylase.
- Patients have been reported in the United States and Europe.
- Age of onset is early infancy (1 to 4 years).
- Characterized by severe photosensitivity, including vesicles and bullae, erosions, excoriations, crusts, and milia; mutilating scarring; and hypertrichosis.

Hepatoerythropoietic Porphyria

HEP is the homozygous/compound heterozygous variant of PCT and results from a profound deficiency of UROGEN decarboxylase.[51] Measurement of the enzyme in hemolyzed whole blood or skin fibroblasts from three unrelated patients with the disease showed that levels were reduced to 7 percent to 8 percent of normal. There is no evidence

as yet to show that clinical expression of HEP is related to exposure to environmental drugs or chemicals, as is true for PCT. Clinical, biochemical, and enzymatic studies of three generations of one family in which a second-generation 31-year-old man was shown to have HEP revealed that both of the proband's parents and each of his three children had a moderate deficiency of UROGEN decarboxylase.[121]

EPIDEMIOLOGY Patients with HEP have been reported in Europe (predominantly in Spain), America, and Japan.

CLINICAL MANIFESTATIONS The disease typically manifests in early childhood, and dark red urine is often the first sign. Severe cutaneous photosensitivity with blistering and pruritus then ensues. The photosensitivity may diminish with age and is followed by hypertrichosis, hyperpigmentation, and scleroderma-like scarring similar to that seen in CEP (Günther disease) (Fig. 132-13). Ocular manifestations include ectropion associated with cutaneous sclerosis and scleromalacia perforans. Splenomegaly has occurred in a small percentage of affected individuals, particularly after the age of 10, and hemolytic anemia has been documented as well. In some patients, liver function test results have been abnormal, but serum iron and iron binding are normal. In summary, the clinical manifestations of HEP resemble a combination of those of PCT and CEP.

LABORATORY FINDINGS The urinary porphyrin pattern is similar to that found in PCT (see Table 132-7). However, elevated RBC PROTO levels in HEP helps to distinguish it from PCT. Elevated levels of urinary URO I and III (URO-COPRO ratio of more than 5:1) and 7-carboxyl porphyrins (more than 90 percent isomer III), elevated levels of fecal COPRO and ISOCOPRO, and elevated levels of RBC PROTO (zinc-chelated) have been observed in all patients. These findings suggest that there is abnormal porphyrin synthesis in both the liver and the bone marrow. Unlike in PCT patients, serum iron concentrations are usually normal in those with HEP.

▲ **FIGURE 132-13** Sclerodermoid thickening and shrinkage of facial and scalp skin with ulcerations and scars in a patient with hepatoerythropoietic porphyria in whom these sclerodermoid changes are particularly pronounced.

HISTOPATHOLOGY Skin biopsy specimens of blistering lesions show sub-epidermal bullae resembling those of PCT, and PAS-positive material is seen in and around dermal capillaries. However, skin biopsy is not essential for making the diagnosis of HEP.

DIFFERENTIAL DIAGNOSIS The differential diagnosis includes childhood porphyrias (e.g., the rare homozygous or compound heterozygous variants of VP and HCP), clinically severe forms of PCT, and CEP. In contrast to patients with HEP, those with CEP show erythrodontia and mutilating scarring.

TREATMENT There is no known treatment aside from careful photoprotection.

Pseudoporphyria

The term *pseudoporphyria* is used to describe patients who clinically exhibit cutaneous manifestations resembling those of PCT without the characteristic abnormal porphyrin profile. This disorder may develop in association with ingestion of certain drugs such as furosemide,[122] nalidixic acid,[123] tetracycline,[124] naproxen,[125] pyridoxine,[126] and isotretinoin[127] (see Chap. 91).

In the drug-induced type of pseudoporphyria, the blistering process is subepidermal with little or no dermal inflammation. Staining with PAS reveals little or no deposition around upper dermal blood vessels and capillary walls. Indirect immunofluorescence studies conducted on split skin reveal no dermal deposition of fluorescent material in pseudoporphyria. Direct immunofluorescence studies have shown patchy granular deposition of immunoglobulin G and C3 at the basement membrane zone in pseudoporphyria, PCT, and epidermolysis bullosa acquisita.

A bullous dermatosis that is morphologically and histologically indistinguishable from PCT has also been observed in patients with chronic renal failure treated with long-term hemodialysis (see Chap. 151). Some of these patients have moderately elevated plasma porphyrin levels (twofold to fourfold) secondary to impaired renal clearance as well as diminished clearance through dialysis filters.

ERYTHROPOIETIC PROTOPORPHYRIA

AT A GLANCE

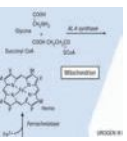
- Second most common of the cutaneous porphyrias.
- Autosomal dominant disorder involving a deficiency of ferrochelatase.
- Age of onset in early childhood (1 to 4 years); rarely late onset can occur.
- Cutaneous findings include erythema, edema, purpura, skin thickening, and waxy scars; blistering is rare.
- Symptoms include acute burning and stinging of the skin that may be severe.
- In approximately 5 percent of patients potentially fatal hepatic failure develops.

Erythropoietic Protoporphyria

EPIDEMIOLOGY Although the exact incidence of EPP is unknown, it has been reported with increasing frequency since its initial recognition in 1961, and it is likely the second most common type of cutaneous porphyria. Studies from one laboratory performing diagnostic tests for RBC porphyrins in patients with suspected cutaneous photosensitivity indicated that 8 percent of such samples demonstrate elevated RBC PROTO levels diagnostic of EPP. The disease occurs globally, and it is likely that no ethnic group is spared.[128]

ETIOLOGY The specific defective enzyme in EPP is ferrochelatase, which is decreased in various tissues of affected patients, including RBCs, mitogen-stimulated lymphocytes, and cultured skin

◀ **FIGURE 132-14** **A.** One hour after exposure to sunlight, the face of this 35-year-old woman with erythropoietic protoporphyria is edematous and erythematous, and there is purpura on the forehead, cheeks, and nose. The patient experiences severe burning sensations. **B.** A case of erythropoietic protoporphyria showing swelling and purpura on the dorsa of the hands resulting from exposure to solar radiation.



fibroblasts of patients with the disorder and unaffected carriers.[129–132] Ferrochelatase is located at the matrix face of the inner mitochondrial membrane and catalyzes the final step in the formation of heme, the incorporation of ferrous iron (Fe^{2+}) into PROTO (see Figs. 132-1 and 132-2). This lysine-rich enzyme has a molecular mass of 63 kd and an optimal pH of 7.8, and is also referred to as *heme synthase* or *proto-heme-ferro-lyase*. Unlike other enzymes in the heme biosynthesis pathway, which require reduced forms of the porphyrins (porphyrinogens) as substrates, ferrochelatase uses PROTO, the oxidized isomer of PROTOGEN. The end product of the pathway, ferrous PROTO or heme, diffuses out of the mitochondrion into the cytoplasm where it is available to function as a prosthetic group by combining with appropriate apoproteins (see Figs. 132-1, 132-3, and 132-4). Heme thus controls its own synthesis based on the needs of the cell.

The cDNA for human ferrochelatase has been cloned, sequenced, and shown to have 88 percent homology to the mouse enzyme. Human ferrochelatase mRNA is encoded by a single nuclear gene of the same name, *ferrochelatase*, that is located on chromosome 18q21.3 and spans approximately 45 kb of genomic DNA.[132] The gene consists of 11 exons and 10 introns. Molecular genetic studies have been conducted in patients with EPP and revealed more than 60 different mutations of various types, with deletions and insertions being the most common. It is of interest that expression of these mutations in bacteria identified a common loss of the iron-sulfur metal center essential for catalytic activity.[133]

Because the activity of ferrochelatase in cultured skin fibroblasts of EPP patients was found to be only 10 percent to 25 percent of normal, questions have been raised about the dominant inheritance of the disease. Studies have now shown that the penetrance of EPP is modulated by expression of wild-type ferrochelatase that contains an intronic single nucleotide polymorphism that results in aberrantly spliced mRNA. Thus, slight variations in expression of the wild-type allele may be decisive in determining clinical expression of EPP. This variable expression of the wild-type ferrochelatase allele is directly associated with the presence or absence of cutaneous symptoms, and it is clear now that EPP occurs only in individuals heterozygous for a *ferrochelatase* gene mutation on one parental allele with a specific intronic *ferrochelatase* polymorphism, IVS3-48T/C, on the other parental allele. On the genetic level this additional nucleotide alteration *in trans* leads to modulation of splicing and the use of a constitutively aberrant acceptor splice site. The aberrantly spliced mRNA is degraded by a nonsense-mediated decay mechanism, which produces a decreased steady-state level of mRNA. On the enzymatic level, this leads to an additional in vivo decrease in residual ferrochelatase activity of 15 percent to 40 percent that diminishes catalytic activity to the point where the EPP phenotype is expressed.[134]

CLINICAL MANIFESTATIONS ***Skin.*** Typically the disease begins early in life and is characterized by acute episodes of cutaneous photosensitivity, including burning, stinging (smarting), and pruritus affecting light-exposed skin, particularly the nose, cheeks, and dorsal aspects of the hands. These symptoms are followed by erythema, edema (Fig. 132-14A), urticarial lesions, and, less commonly, purpura (see Fig. 132-14B). Symptoms may occur within minutes of sun exposure. Manifestations are often seasonal, starting early in the spring, continuing through the summer, and diminishing in the winter. The skin lesions often resolve slowly, leaving small, atrophic, waxy or pitted scars (Fig. 132-15). There may be some pursing of perioral skin (pseudorhagades). The skin of the knuckles and fingers, particularly over the metacarpophalangeal and interphalangeal joints, often appears thickened, wrinkled, and waxy, suggesting a premature aging (so-called *old knuckles*, in a child). This subtle change is pathognomonic. Superficial scarring over the bridge of the nose and small annular shallow scars occur on the face. Vesicular or bullous lesions are rare in temperate climates, although they have been reported in patients exposed to tropical sunlight. In most affected individuals cutaneous involvement persists throughout life, although some patients seem to become less symptomatic over time.

▲ **FIGURE 132-15** A 15-year-old patient with erythropoietic protoporphyria with severe sensitivity to light. The nose, lower lip, and chin show erythematous, in part erosive, and crusted lesions. Nose and cheeks show erythematous lesions, a few small slightly depressed scars, and peculiar waxy thickening of skin. Linear scars are seen between the nose and mouth and on cheeks and face.

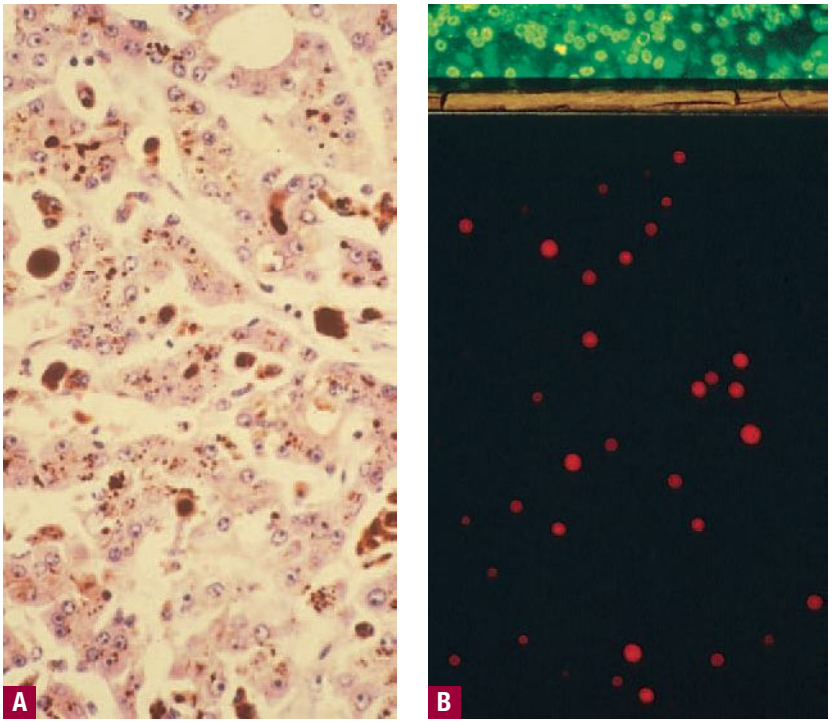
Liver. Severe life-threatening hepatotoxicity occurs in a small percentage of patients with EPP. This is thought to relate to the hepatic clearance of the excessive burden of PROTO, which ultimately compromises liver function. This may be aggravated by hemolysis of PROTO-laden RBCs, which creates a vicious cycle of increased erythropoiesis and increased PROTO loading of the liver. The net result of these alterations is terminal hepatic failure in approximately 5 percent of EPP patients.[135] Affected individuals become severely jaundiced, develop hepatic cirrhosis, and may go into hepatic coma and die. Some EPP patients with end-stage liver disease may develop axonal neuropathy resembling that in the acute hepatic porphyrias despite having normal serum ALA and PBG levels.[136] Risk factors for EPP-associated hepatic failure remain unknown, but parenchymal crystallization of incompletely cleared hepatic PROTO is a likely explanation. Experimental studies have shown that perfusion of rat liver with PROTO induces a dose-dependent cholestasis that could contribute to the hepatotoxicity of PROTO.[137] Liver failure has also occurred in two siblings who inherited EPP in an autosomal recessive pattern as compound heterozygotes, which suggests that the presence of this genotype may somehow augment the risk of this complication.[138] This is debatable, however, because some compound heterozygotes maintain normal liver function, whereas others develop liver failure.[139]

The cutaneous and hepatic symptoms are the major findings in EPP. There is no hypertrichosis, milia, sclerodermoid change, or hyperpigmentation as in PCT, and no erythrodontia as in CEP. Hemolytic anemia is decidedly uncommon, although approximately 11 percent of patients with EPP have a mild anemia of unknown cause.[128] Gallstones have been reported in some patients with EPP at a relatively early age; in one series, 12 percent of patients had cholelithiasis, of whom three underwent cholecystectomy.[140]

LABORATORY FINDINGS The diagnosis of EPP is based on the detection of elevated levels of free PROTO in the RBCs and/or feces (see Tables 132-2 and 132-7). Controversy exists concerning the tissue origin of the excessive PROTO. Some have shown that RBC PROTO levels alone are sufficient to explain the increased levels of PROTO,[24,141] whereas others have suggested that hepatic PROTO production contributes to the excessively high levels of circulating PROTO.[142] In addition, there may be increased plasma PROTO levels, increased fecal COPRO levels, and occasionally slightly increased levels of RBC COPRO. In patients with deteriorating hepatic function the fecal excretion of PROTO may decrease as plasma levels and cutaneous photosensitivity increase.[143]

Examination of a blood smear under a fluorescent microscope reveals red-fluorescing RBCs (5 percent to 30 percent) (Fig. 132-16). Because the fluorescence is often transient and quite light sensitive, the procedure should be carried out in subdued light or preferably in the dark. However, this is not a reliable diagnostic test, because RBCs from patients with chronic lead intoxication also show fluorescence.

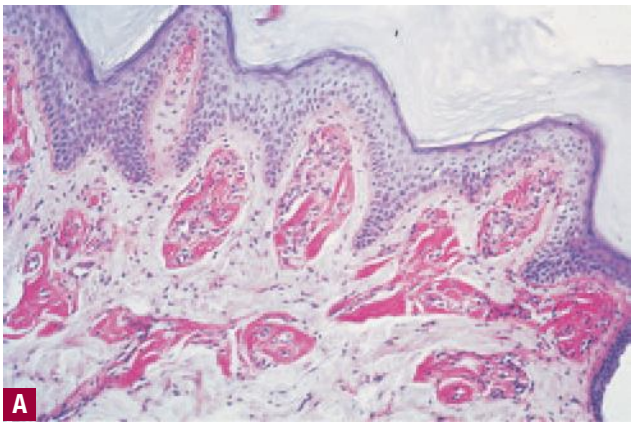
A rapid quantitative microfluorometric assay for free erythrocyte and plasma PROTO may be used to screen for suspected EPP.[144] In one series of 32 patients with EPP, the RBC PROTO levels ranged from 131 to 1617 μg/dL of RBC (normal is less than 90 μg/dL of RBC).[145]

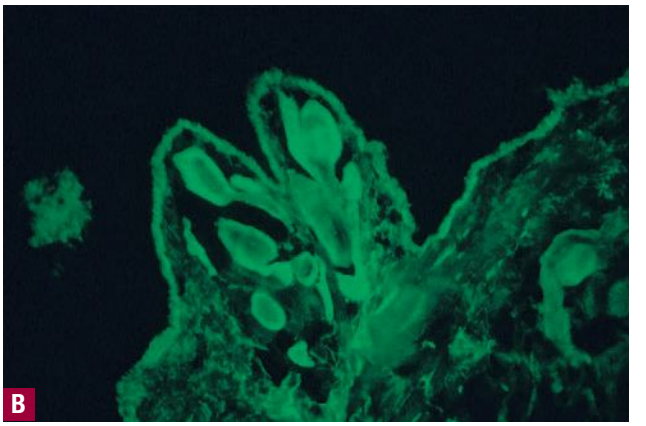


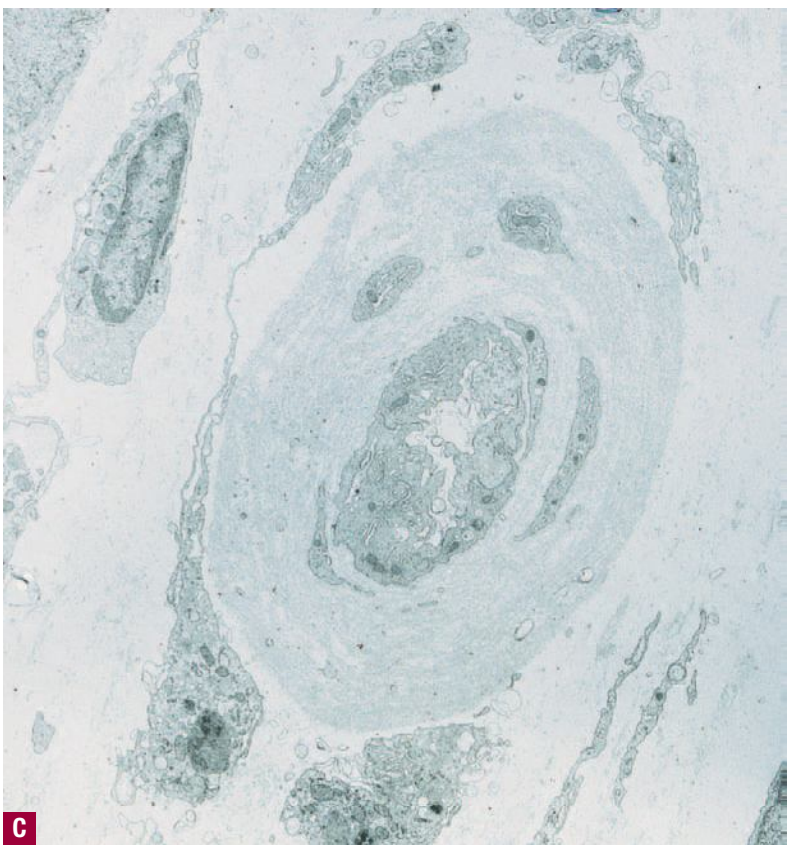
▲ **FIGURE 132-16** **A.** Brown pigment deposits in the liver tissue found in bile canaliculi, hepatocytes, and Kupffer cells. **B.** Bright red fluorescence in red blood cells (RBCs) of a fresh smear from a patient with erythropoietic protoporphyria. Whereas almost all RBCs contained in this smear are revealed by green fluorescence only (*top*), a few RBCs contain increased amounts of protoporphyrins and thus fluorescence in red (*bottom*).

HISTOPATHOLOGY ***Skin.*** Immediately after irradiation, endothelial cell damage, mast cell degranulation, and polymorphonuclear cells are seen in the dermis.[33] In sun-exposed areas, there is often marked eosinophilic homogenization and thickening of vessels in the papillary dermis due to the accumulation of an amorphous, homogeneous, slightly basophilic (hyaline-like) substance in and around the vessel walls.[128] The perivascular deposits of concentric eosinophilic layers of hyaline-like material stain strongly positive with PAS and are diastase positive (Fig. 132-17). Histochemical studies suggest that this material may be a neutral glycoprotein with smaller amounts of acid mucopolysaccharide and lipids.[146] The histologic findings are similar to those of lipoid proteinosis (hyalinosis cutis et mucosae).[147] Electron microscopic studies in EPP show that the amorphous material consists of a multi-layered, partially fragmented basement membrane and finely fibrillar material of moderate density that permeates and surrounds the vessel walls (see Fig. 132-17).[148] Other studies have shown that type IV collagen and laminin as well as amyloid P and fibronectin are deposited in the walls of dermal blood vessels.[149]

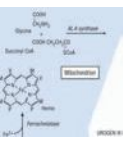
Liver. Light microscopy of liver biopsy specimens has revealed slight portal and periportal fibrosis and deposition of brown pigment, which may occlude bile







◀ **FIGURE 132-17** **A.** A biopsy specimen of light-exposed skin from a patient with erythropoietic protoporphyria. There is marked thickening of the blood vessel walls of the upper dermis, which are surrounded by hyaline-like materials that stains brightly red with the periodic acid-Schiff (PAS) stain. **B.** Direct immunofluorescence testing reveals that the PAS-positive material around papillary vessels contains immunoglobulins of different classes. Immunoglobulins are also deposited along the dermal-epidermal junction. **C.** Electron micrograph of biopsy specimen of habitually exposed skin from a patient with erythropoietic protoporphyria. Multiple concentric basal laminae surrounding dermal blood vessels and finely fibrillar material admixed with amorphous masses within perivascular tissue are shown.



canaliculi and ducts; it is also present in hepatocytes, in Kupffer cells, and in periportal macrophages. The pigment is birefringent on polarization microscopy.[150] Hepatocytes may also contain cytoplasmic or mitochondrial inclusions, which at the ultrastructural level appear as needle-like crystals (Maltese crosses), probably due to precipitated PROTO (see Fig. 132-16).[151] Biliary excretion of PROTO is coupled to secretion of phospholipid translocated from the inner to outer canalicular membrane leaflet by the mdr2P glycoprotein.[133] PROTO excretion from the liver requires bile acids, and excessive amounts of the porphyrin inhibit its transport out of the hepatocyte.

DIFFERENTIAL DIAGNOSIS EPP must be differentiated from other photosensitivity diseases, primarily polymorphic light eruption (PMLE), actinic prurigo, hydroa vacciniforme, idiopathic solar urticaria, and other types of porphyria. Photoallergic and phototoxic contact dermatitis and angioedema should also be considered.

In PMLE, the lesions are characteristically papules, plaques, and papulovesicles. A family history of photosensitivity is less common. Burning and smarting of the skin during or soon after sun exposure is unusual in PMLE, whereas it is common in EPP. If doubts persist, RBC PROTO measurement or plasma porphyrin determination will differentiate the two. The same is true for idiopathic solar urticaria. Airborne contact dermatitis may involve non–light-exposed areas such as the skinfolds and the submental areas. Results of patch testing with suspected allergens and normal porphyrin values help to differentiate this condition. The lesions of angioedema may occur anywhere on the body, including the mucous membranes. Because the discomfort described by patients with EPP is often disproportionate to visible lesions, the disease can be confused with psychoneurosis or even malingering. Porphyrin determinations will clarify this issue.

TREATMENT (See Box 132-1)

Skin Manifestations. Topical sunscreens, such as products containing ecamsule (Mexoryl), titanium, or zinc oxides, are at best only marginally helpful. Other sub-

stances (e.g., antimalarial drugs, cholestyramine, and vitamins E and C) have been suggested but are of unproven benefit.

Although its efficacy has not been confirmed by double-blind placebo-controlled trials, tolerance to sunlight in some patients with EPP may improve with the use of orally administered β-carotene.[152,153] Many patients claimed to triple their tolerance to sunlight after an adequate course of β-carotene exceeding 2 months. These results, however, are based on limited controlled laboratory testing and uncontrolled clinical impressions; the one controlled clinical trial failed to confirm the therapeutic effectiveness of β-carotene although the adequacy of the dosage used has been questioned.[154] To achieve optimal photoprotection, serum carotene levels should be maintained at a minimum of 600 μg/dL. In adult patients, this can usually be achieved by oral administration of two to six capsules of 30 mg each per day, which will produce serum carotene levels of 600 to 800 μg/dL after 4 to 6 weeks of therapy. Children under 12 years of age may receive 30 to 90 mg daily. Maximum effectiveness may not occur until 1 to 2 months after initiation of therapy; hence patients should be treated throughout periods of greatest sun exposure. The drug is remarkably well tolerated at these dosages, and there are no known toxic systemic effects of β-carotene. Diarrhea occurs in a small number of patients. Orange or rusty discoloration of the stools is common and is not an indication for discontinuing treatment. The only other side effect of note is the visible yellowing of the skin that occurs as a result of carotenoderma, and this is more noticeable on the palms and soles. The mechanism of the photoprotective effect of β-carotene is not precisely known. One study involving cultured keratinocytes showed that β-carotene can suppress induction of matrix metalloproteinases (MMPs), including MMP-1, MMP-3, and MMP-10, and that these effects are mediated by quenching of singlet oxygen–mediated induction of MMPs.[155] A further study using microarrays showed that β-carotene inhibited ultraviolet A–induced extracellular matrix degradation.[156]

The amino acid cysteine has been shown to reduce photosensitivity.[157] Hematin infusions may decrease the production of heme temporarily and are associated with a decrease in fecal and plasma PROTO levels in some patients.[141] The use of RBC exchange with autologous washed cells has also been explored for its ability to induce clinical and biochemical remission of EPP. In one patient with EPP, such therapy resulted in a marked decrease in photosensitivity associated with a decline in free erythrocyte PROTO levels.[158]

In summary, the currently available treatments for EPP are not optimal and do not address the underlying molecular pathogenesis of the disease.

Liver Disease. Management of EPP-associated hepatic failure is particularly challenging. Orally administered bile salts may diminish the enterohepatic re-circulation of the excessive PROTO and thereby enhance the clearance capacity of the liver.[159] Oral administration of iron was tried in one patient who manifested incipient hepatic failure as well as elevated erythrocyte and plasma PROTO levels with concomitant iron deficiency anemia, but this therapy proved ineffective.[160] In another patient, oral iron therapy exacerbated the disease.[161] Liver transplantation has also been used, and the 5-year patient survival rate is good, but recurrence of EPP liver disease appears to diminish long-term graft and patient survival.[162,163] Future therapy could include recombinant enzyme replacement of defective ferrochelatase.[164] The feasibility of obtaining detectable levels of the enzyme in fibroblasts from EPP patients by adding the cDNA for normal ferrochelatase using a retroviral vector has been demonstrated.[164] Gene replacement has been achieved in a mouse model of EPP in which ex vivo pre-selection of hematopoietic stem cells transduced with a polycistronic retrovirus expressing human ferrochelatase resulted in complete correction of skin photosensitivity.[165]

Congenital Erythropoietic Porphyria

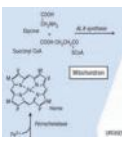
EPIDEMIOLOGY CEP occurs globally. Fewer than 500 cases have been reported. The disease nearly always begins in childhood, although adult onset can occur.[166] CEP is also seen in animals, including swine, cattle, and cats, and studies in these animal models have greatly aided research into this disease.

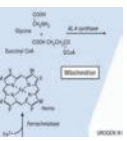
ETIOLOGY CEP is a disorder with an autosomal recessive pattern of inheritance that results from a variable but profound deficiency of UROGEN III synthase, the fourth enzyme in the heme synthetic pathway, which catalyzes the formation of UROGEN III from hydroxymethylbilane or from PBG if PBG deaminase is also present. The only difference between porphyrinogen isomers I and III is the reversal of the side chains on the D ring of this tetrapyrrole. By simple inversion of one PBG molecule during synthesis of UROGEN I, the III isomer is formed (see Fig. 132-2). This apparently minor structural alteration is of considerable biologic importance, because only III isomers can form heme. The formation of UROGEN III is catalyzed by the cytoplasmic enzyme UROGEN III synthase, closely linked to PBG deaminase. This enzyme has been purified from human erythrocytes, is monomeric, and has a molecular mass of approximately 29.5 kd; it is thermolabile and exhibits maximum catalytic activity at pH 7.4.[167] In most tissues, UROGEN III synthase is present in considerable excess compared with PBG deaminase, which assures efficient conversion to the III isomer. The hepatic and erythroid forms of the enzyme are identical.

The human gene for UROGEN III synthase is encoded by a single-copy gene of the same name, *UROGEN III synthase*, that consists of 10 exons and is located on chromosome 10q25.3-26.3. Human UROGEN III synthase cDNA has been cloned and sequenced and encodes a protein of 265 amino acids.[168] To date, approximately 30 mutations in the *UROGEN III synthase* gene have

CONGENITAL ERYTHROPOIETIC PORPHYRIA AT A GLANCE

- Very rare (approximately 200 patients reported).
- Autosomal recessive disorder involving a deficiency of uroporphyrinogen III synthase.
- Age of onset in infancy or first decade of life.
- Cutaneous manifestations include vesicles and bullae, erosions, crusting, milia, mutilating scarring, hyperpigmentation, and hypertrichosis.
- Systemic findings include hemolytic anemia and hepatosplenomegaly.
- Porphyrin deposition occurs in bones and teeth (erythrodontia).





▲ **FIGURE 132-18** Two cases of congenital erythropoietic porphyria (Günther disease). **A, B.** Severe scarring damage of the ear and nose cartilage, hair loss, and discolored teeth. (Used with permission from A. Wiskemann, MD, and J. Kimmig, MD.) **C.** Skin fragility, blisters, erosions, and contractures due to severe scarring on the hands.

been identified, including several in the erythroid-specific promoter.[169]

CLINICAL MANIFESTATIONS The disease usually develops during the first few months of life with moderate to severe cutaneous photosensitivity associated with pinkish red urine.[170] Patients have excessive URO I and COPRO I in RBCs, plasma, and skin.

CEP is the most mutilating of the cutaneous porphyrias. Cutaneous manifestations include skin fragility and vesicles and bullae, which may contain pink fluorescent fluid. Secondary infection, delayed healing, and scarring is common. This may lead to loss of acral tissue, such as the tips of the ears, the nose, and the fingers (Fig. 132-18), and facial mutilation. Hirsutism with long, dark, lanugo-like hair may occur and is particularly evident in light-exposed areas such as the face, neck, and extremities. The scalp may develop a cicatrizing alopecia. Other findings over the disease course include eye changes (photophobia, keratoconjunctivitis, ectropion, symblepharon, and even loss of vision) and irregular hyperpigmentation and hypopigmentation of the skin. Erythrodontia (red-stained teeth) is a common finding in both deciduous and permanent teeth and is virtually pathognomonic of CEP. The urine may also fluoresce reddish pink.

Associated non-cutaneous findings include splenomegaly, porphyrin-rich cholelithiasis, and fluorescent bone marrow normoblasts. Hemolytic anemia associated with shortened erythrocyte life span (36 vs. 120 days) and hypersplenism occurs. Whether the hemolytic anemia is due to "photohemolysis" of circulating porphyrin-laden erythrocytes or to an associated intracorpuscular red cell defect is unresolved.[171]

LABORATORY FINDINGS The primary defect in CEP is decreased UROGEN III synthase activity, which results in accumulation of predominantly type I porphyrins in the tissues. The pink to burgundy red color of the urine from excess URO I is often visible on inspection. Marrow normoblasts exhibit relatively stable fluorescence and contain markedly elevated levels of URO I, COPRO I, and PROTO. Urinary excretion of ALA and PBG is normal. COPRO I may be present in large amounts in the feces. The typical biochemical findings of CEP are summarized in Table 132-7.

HISTOPATHOLOGY The bullous lesion of CEP is sub-epidermal with minimal degrees of inflammation. Thickening of collagen bundles may be seen in areas of scarring. Perivascular deposits of porphyrin can be found when the unstained sections of skin or liver are viewed with a fluorescence microscope.

DIFFERENTIAL DIAGNOSIS The diagnosis of CEP can usually be made from the early onset of severe cutaneous photosensitivity associated with reddish pink fluorescent urine and erythrodontia. Distinguishing CEP from other congenital photodermatoses is important. Cutaneous findings in patients with xeroderma pigmentosum, epidermolysis bullosa, hydroa vacciniforme, and bullous pemphigoid may mimic those of patients with CEP, but porphyrin analysis will distinguish them.

Patients with chronic hepatic porphyrias such as PCT and VP have normal RBC PROTO levels. The cutaneous manifestations of HEP may be strikingly similar to those of CEP, and measurement of levels of RBC UROGEN III synthase (decreased in CEP) and UROGEN decarboxylase (decreased in HEP) will distinguish the two. The dual occurrence of HCP and CEP in a single patient who inherited the HCP trait from her mother and the CEP trait from both of her parents has been reported.[172]

TABLE 132-8
Overview and Summary of the Features of the Acute Porphyrias

	Acute Intermittent Porphyria	Variegate Porphyria	Hereditary Coproporphyria	ALA Dehydratase Deficiency Porphyria
Synonym(s)	Swedish porphyria	Mixed porphyria, South African genetic porphyria, protocoproporphyria hereditaria, PCT hereditaria	Idiopathic coproporphyria	Plumboporphyria.
Inheritance	Autosomal dominant	Autosomal dominant	Autosomal dominant	Autosomal recessive.
Age of onset	10–40 yr; extremely rare before puberty	Usually between ages 15 and 30 yr	Any age	Early and late clinical onset has been described.
Incidence	1.5 in 100,000; more common in Scandinavia and Lapland	Common in South Africa (3 in 1000); relatively rare elsewhere	Rare (fewer than 50 cases reported)	None.
Photosensitivity	Absent	Moderate to severe with high interindividual variation; similar to that in PCT	Very rare	Absent.
Skin reactions (on sun-exposed areas)	None	Vesicles and bullae, erosions, crusts, milia, scarring, hypertrichosis; similar to those in PCT	Usually blistering	None.

ALA = δ-aminolevulinic acid; PCT = porphyria cutanea tarda.

TREATMENT (See Box 132-1) The treatment of CEP is essentially preventive and symptomatic and includes avoidance of sun exposure, surveillance of the anemia, and treatment of recurrent skin infections. Absolute protection from sunlight using photoprotective clothing may be of substantial benefit. Topical sunscreens have no proven efficacy. Oral β-carotene (120 to 180 mg daily) is not effective. Splenectomy performed to relieve intractable hemolytic anemia has occasionally resulted in marked improvement of both the anemia and cutaneous photosensitivity. Suppression of erythropoiesis by transfusion of packed erythrocytes can diminish porphyrin production and excretion,[173] but secondary iron overload is of concern. Oral administration of activated charcoal to a single patient (60 g three times a day) for 9 months decreased porphyrin levels in plasma and skin and resulted in complete remission of photosensitivity during the treatment period.[174] Charcoal is thought to interfere with the enterohepatic recirculation of the porphyrin. This beneficial effect has been disputed, however.[175] Allogeneic bone marrow transplantation has been curative for a small number of patients and thus seems to be the current first-line treatment.[176,177]

THE ACUTE PORPHYRIAS (Table 132-8)

Acute Intermittent Porphyria

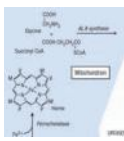
EPIDEMIOLOGY AIP occurs globally. The incidence in the human population is approximately 1 to 2 in 100,000, although it is much higher in Scandinavia, particularly Lapland (1 in 1000).[178] AIP rarely, if ever, manifests before puberty. Most published series emphasize the female predominance of affected patients, ranging from 1.5:1.0 to 2:1.[7]

ETIOLOGY AIP is due to a deficiency of PBG deaminase, the third enzyme in the heme biosynthetic pathway (see Figs. 132-1 and 132-2). This enzyme combines four molecules of the monopyrrole PBG to form the linear tetrapyrrole hydroxymethylbilane, which cyclizes spontaneously to form the initial porphyrinogen, or tetrapyrrole, known as UROGEN I (see Fig. 132-2). Depending on the manner in which the PBG molecules are arranged, several different isomers of the tetrapyrroles are possible. The sole difference between type I and type III porphyrinogens is that one of the four pyrrole rings is "flipped over." Only two of them (designated I and III) are known to occur in the mammalian heme synthetic pathway. PBG deaminase has been purified from human RBCs and shown to have a molecular mass of approximately 37 kd and a pH optimum of 8.2.[179] In AIP patients, PBG deaminase activity is approximately 50 percent of that in unaffected normal individuals, consistent with an autosomal dominant mode of inheritance. Diminution of PBG deaminase levels partially blocks heme synthesis, which in turn decreases the regulatory heme pool and leads to de-repression of ALA synthase mRNA synthesis.

The *PBG deaminase* gene has been cloned and characterized.[180] Two isoforms, one ubiquitous and one erythroid specific, are encoded by a single gene localized to 11q23→11qter.[3] It comprises 15 exons spread over 10 kb of DNA. The two isoforms of the enzyme are encoded by two distinct mRNAs that arise from two overlapping transcription units. The first (upstream) is active in all tissues and its promoter has some features of a housekeeping promoter, whereas the second, located 3 kb downstream, is active only in erythroid cells and displays structural homology with β-globin gene promoters. Differential splicing gives rise to two isozymes of slightly different molecular sizes.[8] To date, more than 200 mutations have been reported at the PBG

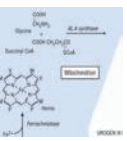
ACUTE INTERMITTENT PORPHYRIA AT A GLANCE

- Most common of the acute porphyrias
- Autosomal dominant disorder involving deficiency of porphobilinogen deaminase
- Frequency as high as 1 to 2 in 100,000
- Age of onset in second to fourth decade of life; rare before puberty
- Acute neurologic attacks but no photosensitivity or cutaneous findings



deaminase locus, including deletions, insertions, and missense, nonsense, and splicing mutations.[181]

PBG deaminase is present in the second lowest concentration of any enzyme in the heme pathway; ALA synthase is in the lowest. This suggests that additional factors (genetic or acquired) that influence PBG deaminase activity may have important regulatory influences on the rate of heme synthesis. Consequently, if excessive PBG is formed because of increased ALA synthase activity, as is often seen in the acute hepatic porphyrias, there may be only partial conversion of this monopyrrole to UROGEN I. These factors account for the elevated urinary PBG levels characteristic of attacks of the acute hepatic porphyrias. PBG deaminase activity is known to be reduced by approximately 50 percent in the tissues of patients with AIP and is currently thought to be the primary enzymatic abnormality in this autosomal dominant disorder. There is a variant form of AIP (occurring in perhaps 10 percent of cases) in which the PBG deaminase defect is restricted to non-erythropoietic tissues due to mutations in exon 1 that are absent from erythroid mRNA.



CLINICAL MANIFESTATIONS (See Table 132-8) Fewer than 10 percent of latent carriers of the PBG deaminase defect ever express the clinical phenotype. Hence, the gene defect alone seems to be inconsequential unless the individual is exposed to additional triggering factors, among which certain drugs that induce hepatic cytochrome P_{450} enzymes are particularly important (Table 132-9).[182,183] The clinical signs and symptoms of AIP may also relate to the effects of excessive porphyrin precursors or to heme depletion in the autonomic nervous system.[5]

An acute porphyric attack is characterized by abdominal pain (in 80 percent to 90 percent of AIP patients) and neurologic and psychiatric symptoms that can mimic those of numerous disorders. The pain may be diffuse or localized and is often intermittent and spastic. Vomiting and constipation are frequently associated. Mild fever and leukocytosis may occur, which makes differential diagnosis extremely difficult. This is one reason many patients with AIP have undergone multiple exploratory laparotomies before the correct diagnosis is established. Between attacks patients are often remarkably symptom free. Attacks are often precipitated by ingestion of drugs such as those listed in Table 132-9. Acute attacks of AIP may be accompanied by seizures, especially in patients with hyponatremia resulting from vomiting and inappropriate fluid therapy. Peripheral neuropathy is a major part of the clinical syndrome in many patients, varying from sensory (localized pain) to motor (weakness progressing to generalized flaccid paralysis).[12,184] Patients may succumb to the disease, usually due to respiratory failure, or may improve slowly, although residual muscle weakness frequently persists for extended periods.

TABLE 132-9
Examples of Drugs Potentially Hazardous in Patients with the Acute Hepatic Porphyrias

Amidopyrine	Isopropylmeprobamate
Aminoglutethimide	Mephenytoin
Aminopyrine	Meprobamate
Amphetamines	Methyldopa
Antipyrine	Methyprylon
Barbiturates	*N*-butylscopolammonium bromide
Bemegride	Nalidixic acid
Carbamazepine	Nikethamide
Carbromal	Nitrazepam
Chloromethazone	Nortriptyline
Chlorpropamide	Novobiocin
Chloroquine	Pargyline
Danazol	Pentazocine
Dapsone	Pentylenetetrazole
Diclofenac	Phenoxybenzamine
Diethylpropion	Phenylbutazone
Diphenylhydantoin	Primidone
Dramamine	Pyrazinamide
Enflurane	Rifampin
Ergot preparation	Sedormid
Erythromycin	Succinimides
Ethchlorvynol	Sulfonamides
Ethinamate	Sulfonethylmethane
Ethosuximide	Sulfonylureas
Ethyl alcohol	Synthetic estrogens, progestins
Fentanyl	Theophylline
Furosemide	Tolazamide
Furoxone	Tolbutamide
Glutethimide	Trimethadione
Griseofulvin	Valproic acid
Halothane	
Heavy metals	
Hydralazine	

Cutaneous photosensitivity does not occur in AIP. This is logical, because the abnormal excretion pattern of the disease consists mostly of the non-photosensitizing porphyrin precursors ALA and PBG.

LABORATORY FINDINGS The primary gene defect in AIP results in PBG deaminase deficiency, which causes excessive urinary excretion of ALA and PBG. Urinary porphyrin levels may also be slightly elevated (see Table 132-3). Urinary excretion of ALA and PBG may be as high as 100 mg/24 hours in an acute attack. During remission urinary excretion of ALA and PBG decreases but usually remains above normal values. This is in contrast to VP and HCP, in which urinary excretion of ALA and PBG is often normal between acute attacks.

Two rapid screening tests are available to test freshly voided urine for increased PBG level. The first is simply to expose the urine to bright sunlight for several hours. Darkening to a deep red color suggests but does not prove that excessive PBG is present, because porphobilin, another dark pigment, can also be photocatalytically formed in urine. The second rapid screening test, known as the *Hoesch test*, is more definitive and involves a simple procedure for detecting excessive urinary PBG.[185] Two drops of fresh urine are added to 2 mL of Ehrlich's reagent (3 g of *p*-dimethylaminobenzaldehyde dissolved in 125 mL of acetic acid and 24 mL of perchloric acid). A uniform cherry-red color of the sample indicates a positive reaction. This test is based on the formation of a chromogen by PBG and Ehrlich's aldehyde reagent that produces a red pigment with strong absorption at 552 nm. The classic Watson-Schwartz test is based on this same principle. The results of these qualitative tests, although potentially useful for screening, must be confirmed by quantitative 24-hour measurement of urinary ALA and PBG using ion-exchange chromatography or high-performance liquid chromatography.[186]

HISTOPATHOLOGY AIP does not manifest cutaneous symptoms.

DIFFERENTIAL DIAGNOSIS The clinical manifestations of AIP are protean and resemble so many different diseases that Waldenström has used the term *little imitator* to describe it.[12,178] Several excellent reviews have summarized the differential diagnosis of AIP,[3,181,187] and because this disorder has no cutaneous findings, it is not discussed further here.

TREATMENT There is no cure for AIP. Management of the acute attack uses multiple approaches, including glucose loading (2 L of 20 percent glucose over 24 hours in divided doses of 500 mL through a central venous line).[119,187,188] Administration of a gonadotropin-releasing hormone analog has also been recom-

TABLE 132-10
Drugs Considered to Be Safe (or Probably Safe) in Patients with the Acute Hepatic Porphyrias

Acetaminophen	Insulin
Adrenaline	Labetalol
Amitriptyline	Lithium
Aspirin	Mandelate
Atropine	Methenamine
Bromide	Naproxen
Cephalosporins	Narcotic analgesics
Chloral hydrates	Neostigmine
Chloramphenicol	Nitrofurantoin
Chlordiazepoxide	Nitrous oxide
Colchicine	Oxazepam
Digoxin	Penicillin and derivatives
Diphenhydramine	Phenothiazines
Ethylenediaminetetraacetic acid (EDTA)	Propranolol
Ether	Prostigmin
Glucocorticoids	Rauwolfia alkaloids
Guanethidine	Streptomycin
Heparin	Succinylcholine
Hyocine	Tetracycline
Hypocine	Thiouracil
Ibuprofen	Thyroxine
Indomethacin	

Box 132-2
Treatment of the Acute Porphyrias

TYPE	MANAGEMENT
Acute intermittent porphyria, variegate porphyria, hereditary coproporphyria, δ-aminolevulinic acid dehydratase deficiency porphyria	Acute attacks • Identification and elimination of precipitating factors (porphyrinogenic drugs, alcohol, hormones) • Monitoring in intensive care unit and/or contacting of specialized porphyria center (centers are available worldwide) • Provision of appropriate analgesia (e.g., with pethidine or other opiate derivatives) • Management of nausea and vomiting (e.g., with promazine, chlorpromazine, or triflupromazine) • Intravenous administration of either heme arginate (Normosang, Europe) in a dose of 3 mg/kg body weight once daily over 4 consecutive days or hematin (Panhematin, USA; see http://www.blooddiagnostics.com/Product%20Inserts/Ovation/panhematin_pi.pdf) • If necessary, intravenous glucose loading • Measurement of excretion of urinary porphyrin precursors (δ-aminolevulinic acid and porphobilinogen) during the acute attack (daily, if possible)
Variegate porphyria, hereditary coproporphyria	Cutaneous manifestations • Photoprotection (e.g., with broadband sunscreens and/or protective clothing) • Avoidance of sunlight exposure and trauma

mended.[189] Intravenous infusion of hematin in the form of heme arginate is effective in shortening attacks.[187] Precipitating factors such as drugs (see Table 132-9), sex steroid hormones, starvation, and so on, should be avoided. AIP patients should wear medical warning bracelets and should be given lists of drugs to avoid. Drugs thought to be safe for AIP patients are listed in Table 132-10.

Currently recommended therapeutic regimens for the treatment of an acute porphyric attack and associated prophylactic measures are described in the following sections. These procedures are applicable for all patients with acute porphyrias presenting with neurovisceral manifestations.

Treatment of Neurovisceral Attacks in the Acute Porphyrias. (Box 132-2) Most patients with acute porphyria experiencing an attack can now be treated successfully, and life-threatening complications such as muscle paralysis, respiratory failure, and coma can be avoided if appropriate aggressive treatment is implemented immediately. Untreated or inappropriately treated patients experiencing an acute porphyric attack may have a 10 percent to 15 percent risk of mortality.[11] Today, with mechanism-based therapeutic intervention, the mortality rate of the acute attack has decreased to approximately 2 percent. There are four major steps in treating an acute porphyria attack.

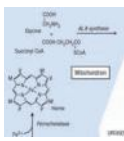
First, all potentially porphyrinogenic drugs should be stopped immediately, and the patient should be monitored carefully and admitted to an intensive care unit if possible. Several sources are available that categorize drugs as relatively safe or unsafe for patients with acute porphyria.[13] Additional information is available on the Internet at the website of the European Porphyria Initiative (EPI) at http://www.porphyria-europe.com.

Second, symptomatic treatment of neurovisceral manifestations like abdominal pain, vomiting, tachycardia, and seizures should be initiated promptly. The following recommendations originate from different sources, including guidelines published by the EPI and a consortium of Northern American porphyria specialists:

SYMPTOM/SIGN	TREATMENT
Abdominal pain	Acetylsalicylic acid; morphine
Vomiting	Chlorpromazine; promethazine
Hypertension and tachycardia	Propranolol
Hyponatremia	Electrolyte balance; saline infusions
Convulsions	Gabapentin
Constipation	Neostigmine

Third, high doses of carbohydrates should be infused intravenously, preferably 400 to 500 g of glucose per 24 hours using 5 percent or 10 percent glucose solutions. Simultaneously, diuresis should be induced by administration of furosemide with careful monitoring of serum electrolyte levels. Patients experiencing an acute attack are often unable to eat or drink because of severe nausea and recurrent vomiting. The rationale for high doses of glucose is based on experimental evidence showing that carbohydrates suppress the induction of ALA synthase, the first and rate-limiting enzyme of the heme biosynthetic pathway. Studies have now shown that ALA synthase is regulated by the peroxisome proliferator–activated receptor-γ coactivator 1α (PGC-1α).[190] Elevation of PGC-1α levels in mice increases the levels of heme precursors in vivo as observed in patients during acute porphyric attacks, whereas the induction of ALA synthase by fasting is lost in liver-specific PGC-1α knockout animals, as is the ability of porphyrogenic drugs to dysregulate heme biosynthesis. These data show that PGC-1α links nutritional status to heme biosynthesis and acute hepatic porphyria and provides a rationale for high-dose glucose infusions. Unfortunately, in many patients this regimen is only partially helpful, and thus glucose infusions are considered to be adjuvant therapy until hematin preparations are available.

Fourth, intravenous administration of heme arginate, currently not approved by the U.S. Food and Drug Administration, is the most efficient method to sup-



press heme synthesis. The rationale for this approach is that intravenous administration of high doses of the end product heme repress the synthesis of ALA synthase.[191] Initially the available hematin preparations were quite unstable and frequently caused thrombophlebitis.[119,192] A newer derivative, heme arginate, consists of human hemin and L-arginine as an additive to increase the solubility and stability of the product. This preparation does not affect coagulation and fibrinolysis, and the frequency of thrombophlebitis as well as the overall rate of side effects is markedly reduced.[193] Heme arginate exerts its specific action by correcting the underlying heme deficiency and restoring the negative feedback control of heme on ALA synthase, thereby decreasing the excessive hepatic production of porphyrins and porphyrin precursors. Heme arginate should be administered intravenously as a short infusion at a dosage of 3 mg/kg body weight per day over a period of 4 days. Administration can be continued cautiously if the attack is not aborted; however, use of heme arginate for more than 7 days is not recommended. In the United States, an alternate form of heme known as *hemin* can be administered for the treatment of an acute porphyric attack. It is currently recommended that hemin administration be considered only after an appropriate period of alternate therapy (i.e., 400 g glucose/day for 1 to 2 days).

Prevention of Attacks. Patients should be advised to avoid fasting or dieting, to abstain from alcohol use, and to be aware of porphyrinogenic drugs, such as barbiturates, sulfonamides, and estrogens, to name several.[13,186] Lists of safe and unsafe drugs are available on the website of the American Porphyria Foundation at http://www.porphyriafoundation.com/about_por/drugs/drugs02.html and, in 10 different languages, on the website of the EPI (see Treatment of Neurovisceral Attacks in the Acute Porphyrias).

Using appropriate screening procedures, asymptomatic family members of individuals with known acute porphyria should be screened for enzymatic deficiency and mutations to help define inheritance patterns and to identify individuals at risk.

Variegate Porphyria (See Table 132-8)

EPIDEMIOLOGY VP occurs worldwide but is most prevalent in South Africa and Chile, mainly due to founder effects in both countries.[5,18,194–196] In South Africa, this form of porphyria is quite common among the Caucasian and so-called *Cape-coloured* South Africans. A high proportion of the present Caucasian population is descended from a pair of early Dutch settlers who emigrated from the Netherlands to South Africa in 1688. The incidence of VP in South Africa is the highest in the world, with the disorder affecting approximately 1 in 300 individuals in the white population.

VARIEGATE PORPHYRIA AT A GLANCE

- Incidence of approximately 1 in 300 in South Africa; relatively rare elsewhere, with the exception of Chile.
- Autosomal dominant disorder involving deficiency of protoporphyrinogen oxidase.
- Age of onset in second to third decade of life; rare before puberty.
- Skin manifestations are indistinguishable from those of porphyria cutanea tarda; acute attacks similar to those in acute intermittent porphyria can occur (neurocutaneous porphyria).
- Founder mutations have been identified in South Africa and Chile.

ETIOLOGY VP results from decreased PROTOGEN oxidase activity and is an autosomal dominant disorder.[197–199] PROTOGEN oxidase is an integral protein of the inner mitochondrial membrane and catalyzes the oxidation of PROTOGEN IX to PROTO, removing six hydrogens from PROTOGEN IX (see Figs. 132-1 and 132-2). This reaction can also occur nonenzymatically, but the enzyme appears to be necessary for normal heme synthesis. The enzyme acts specifically on PROTOGEN IX, the penultimate step in heme synthesis. COPROGEN I or III and UROGEN I or III are not substrates for this enzyme. PROTOGEN oxidase isolated from rat liver mitochondria has been shown to have a molecular mass of 51 kd and requires molecular oxygen to catalyze the oxidation of PROTOGEN to PROTO.

Human PROTOGEN oxidase is encoded by a single-copy gene of the same name, *PROTOGEN oxidase*, that has been mapped to chromosome 1q22-23, spans 8 kb, and consists of 13 exons. Northern blot analyses of specimens from a variety of tissues indicate that there is a single transcript of 1.8 kb encoding a protein of 477 amino acids.[200] Multiple mutations have been identified, including founder mutations in South Africa (R59W) and Chile (1239delTACAC).[19,201]

CLINICAL MANIFESTATIONS The clinical manifestations of VP encompass those of both PCT and AIP, which can occur simultaneously or separately in the same individual. The major difference between VP and PCT is that skin signs and symptoms usually develop at an earlier age in VP (second and third decades) than in PCT (fourth and fifth decades). The major difference between VP and AIP is that acute attacks are much less common in VP. In South Africa, excessive intake of home-brewed spirits (Kaffir beer) and dietary iron overload from cooking vessels are considered important factors in the development of clinically overt disease. Thus, VP occurring in the descendants of the Dutch immigrants of South Africa is quite distinct from the PCT seen in the native black population. As pointed out by Dean for a group he designated as *Cape-coloured*, (descendants of white European and Indian immigrants who intermarried with black natives), VP and PCT may co-segregate in the same family.[202]

Skin Lesions. The cutaneous lesions of VP are indistinguishable from those of PCT and HCP. These include bullae and erosions on light-exposed skin (Fig. 132-19). Hyperpigmentation, milia, hypertrichosis, and increased skin fragility are also seen. They appear to be more common in the hot climate of South Africa and are less frequently seen in affected individuals in colder climates. Blisters are often blood tinged, heal slowly, and heal with scarring and milia formation. Occasionally the patient gives a history of acute sun sensitivity that occurs during or soon after a period of exposure; this may include burning, erythema, and edema. In the chronic state, the skin changes may include thickening and scarring (Fig. 132-20). Some believe that melanin pigmentation may reduce the severity of the photocutaneous findings. The skin manifestations do not correlate with the acute attacks in most patients, and in general,

▲ **FIGURE 132-19** Large bullae on the dorsum of foot and toes of a patient with variegate porphyria. Note that these patients also develop pigmentary changes and milia just as in porphyria cutanea tarda.

males are more likely to have the PCT-like skin findings, whereas females are more prone to AIP-like acute attacks.

Neurovisceral Symptoms. Neurovisceral symptoms are identical to those occurring in AIP and consist of attacks of abdominal pain, constipation, vomiting, muscle weakness, and neuropsychiatric manifestations of stupor and coma. Factors that trigger attacks of AIP also appear to induce VP (various drugs, starvation, etc.). All patients with the skin findings of PCT should be screened for VP because of its life-threatening potential.

These clinical features rarely develop before puberty, except in the rare homozygous patients who may develop cutaneous signs and symptoms at or shortly after birth. In addition to the early onset of skin symptoms, for unknown reasons these patients frequently manifest short stature and small hands with shortening of the digits.[203–205]

▲ **FIGURE 132-20** South African patient with variegate porphyria showing photodamage as in porphyria cutanea tarda but changes that are less severe than in Caucasians.

LABORATORY FINDINGS Urinary ALA and PBG levels are elevated during acute attacks of VP (when results of the Watson-Schwartz test may be positive) but characteristically fall to normal levels between attacks (see Table 132-3), whereas in AIP patients, urinary ALA and PBG levels are elevated both during and between attacks. Another feature distinguishing the two disorders is stool porphyrin excretion. Asymptomatic patients with VP usually, but not always, have marked elevations of stool PROTO and COPRO levels between attacks.[206] These may fluctuate somewhat during acute attacks, and PROTO typically exceeds COPRO. In AIP, fecal levels of porphyrins are not elevated between attacks and usually increase only slightly during attacks. Certain patterns of fecal and urinary porphyrin excretion may help in distinguishing VP from PCT.[207] URO in the urine is only moderately elevated in VP, and urinary COPRO level typically exceeds URO level. This is in marked contrast to active PCT, in which the reverse is seen (i.e., urinary URO level is usually several-fold higher than COPRO level). Again in VP, fecal porphyrins usually exceed 500 μg/g dry weight in more than 90 percent of patients, whereas in PCT this amount of stool porphyrin is excreted by only 1 percent of patients. Furthermore, the ratio of stool PROTO to COPRO in VP usually exceeds 1.5:1.0, whereas in PCT the ratio is almost always less than 1:1 due to the increased ISOCOPRO content characteristic of the latter disease. However, stool porphyrin excretion patterns consistent with both VP and PCT have been found in different members of single families.[61,62] These types of findings have led to the suggestion that measurement of bile porphyrins may be decisive in confirming a diagnosis of VP when excretory porphyrin patterns are ambiguous.[100] Saline-diluted plasma specimens from patients with VP have characteristic fluorescence emission spectra (626 nm emission peak) that can be used to differentiate this disease from other forms of acute porphyria, PCT, EPP, and lead poisoning (see Table 132-4).[208]

HISTOPATHOLOGY The histopathologic alterations in VP are indistinguishable from those in PCT.

DIFFERENTIAL DIAGNOSIS The differential diagnosis of VP should be considered from two perspectives. The skin lesions of VP are identical to those of PCT, and because of this, the differential diagnosis includes the bullous diseases as well as other photosensitivity disorders. HEP must also be considered, but the latter usually begins in early childhood and is characterized by markedly deficient erythrocyte UROGEN decarboxylase activity and elevated erythrocyte PROTO levels as well as increased stool ISOCOPRO levels. The presence of skin lesions rules out AIP. The determination of urinary ALA and PBG concentrations may help to rule out PCT and HEP. Screening of family members by measuring fecal porphyrins may also be helpful in differentiating VP and PCT.

Acute attacks of abdominal pain and neurologic signs and symptoms are identical to those described for AIP (see Box 132-2). Fecal and biliary PROTO and COPRO measurements and determination of plasma fluorescence spectra are decisive in making the diagnosis. In HCP there may be identical acute attacks, but markedly elevated fecal COPRO III levels are diagnostic for this disease.

TREATMENT Preventive and symptomatic treatment of the acute attacks in VP is identical to that described for AIP, including avoidance of inducing drugs (see Table 132-9) and glucose loading as well as hematin infusions. Unlike in PCT, there is no evidence of iron overload in VP, and therefore phlebotomy and antimalarial drugs are ineffective.[209]

Hereditary Coproporphyria (See Table 132-8)

EPIDEMIOLOGY Although apparently rare, HCP occurs worldwide and, like AIP, affects females more than males. To date, fewer than 50 patients have been reported. In addition to classic HCP, an extremely rare form of porphyria, designated *harderoporphyria*, has been described. This disease is a homozygous variant of HCP in which COPROGEN oxidase activity is very low (10 percent of control values).[210–212]

ETIOLOGY HCP is an autosomal dominant disorder resulting from a decrease in the residual catalytic activity of COPROGEN oxidase (see Figs. 132-1 and 132-2).[213,214] The enzyme is localized in the intermembrane space of the mitochondrion, has a molecular mass of 74 kd, and catalyzes the conversion
